conclusion transcends both figurative and operative understanding of the concept of a square in that a relationship with another figure has been established. In a traditional geometry curriculum, this relationship can only be meaningfully constructed through deductive reasoning. However, the use of dynamic geometric software allows for the construction of this relationship through visual inductive reasoning. In a sense, these types of hierarchical relationships once a product of VR discourse become products of AR discourse through perceptual mediation using the on-screen carriers for the relational prototype.

In general the relationship between concrete carrier and prototypes is particularly important in a dynamic geometry environment. Furthermore, although each type of prototype consists of certain characteristics with varying degrees of complexity, there is not a hierarchical or sequential relationship between them. In other words the acquisition of one type of prototype is not a prerequisite, nor does it necessarily lead to the construction of another. Rather they are networked in a non-linear manner to give meaning to more complex concepts. This framework diverges from more typical frameworks like the Van Hiele levels for geometric understanding (Bell, 1998; Frerking, 1994) and the SOLO taxonomy (Olive, 1991; Pegg & Davey, 1998) used in many of the previous research studies on geometry. Given the need to describe the dynamic nature of the geometric representations we chose to depart from these frameworks to explore the nonlinear development of meaning and prototypes. According to Doerfler (1991), the development of meaning has a holistic aspect corresponding to the prototype for the respective concept in which development is not divided up into more elementary particles or ideas to be progressed through sequentially. Rather, to attain meaning, suitable concrete carriers must be developed and presented to the students in a manner and context to promote the construction of the appropriate prototype.

### **Methodology**

This study took place in a fifth grade classroom (25 students) in a large Midwestern elementary school (approximately 700 students) at the beginning of the second semester. The study began with careful observations of one teacher's current pedagogical practice in a technology-rich fifth grade classroom. One important characteristic of this classroom was the emphasis on technology in all curricular areas. Students had access to a classroom lab of desktop computers, a classroom set of laptops with wireless Internet connections, and digital video cameras with digital video editing software. Students used some form of digital technology on a daily basis through the creation and maintenance of their own personal web page portfolios. It was common for the teacher and students to video tape their own classroom activities, edit the video clips, and post them on their web page. Furthermore, all the video taping and digital editing were done by the students. This technology-rich classroom provided a context that was conducive to this project's use of a computer-based geometry curriculum and video technology for the collection of data.

A total of eleven 45-minute lessons were co-taught by one of the researchers and the classroom teacher. Their role was to act as a facilitator for learning between a dynamic geometry curriculum called Shape Makers (Battista, 1998) and the students. Each class session consisted of two parts. For the first 30 minutes, students were given a set of tasks that they were to complete either individually or in pairs using the Shape Maker curriculum. During the last 15 minutes, a whole class discussion, facilitated by one of the researchers was used to help summarize and synthesize the concepts from the day's activities. After one week of whole class instruction and discussion, two students from the classroom were then asked to participate in case-study observations during the second week of instruction. The two students worked on the program together while one member of the research team member interacted and ask occasional questions for clarifying how the students were interpreting, following the instruction or working on some task.

As the students worked on the computer, all on screen work and dialogue was captured on a digital video recorder to document the on screen actions with the discourse between the two students (Hall, 2000; Lesh & Lehrer, 2000). The purpose of videotaping individual students was to identify any idiosyncratic interactions with the computer based lessons. The following results and discussion are based on two days worth of video taped material taken during the second week of instruction.

### Results

In the first videotaped session, after exploring the properties of the sides and angles in square maker and rectangle maker, the students moved on to the parallelogram maker. When they first opened up the parallelogram maker, their initial observation was the unequal angles in the parallelogram. However, their first action on the parallelogram maker was to make it into a square. This important action, making the parallelogram maker into a square or rectangle, was done repeatedly with the other shape makers throughout their investigation. The choice of square and rectangle as referent objects makes sense in that the students seemed to have the most formal and informal knowledge about both shapes that was reinforced by their exploration with the square and rectangle makers. During the second videotaped session, the students' construction of figurative and relational prototypes was extended through their investigation with the trapezoid maker. While working with the trapezoid maker, the students observed that all the sides were not congruent. The two students begin to discuss properties of parallel sides, non-parallel sides, and side length. In the midst of this discussion, Student J then proceeded to turn the trapezoid maker into a parallelogram by making the two non-parallel sides parallel.

Student J: [At this moment, two sides of the trapezoid are not parallel]...they won't be the same, here, ok, ready...they intersect on D and C...right...there [Now, she drags one vertex of the trapezoid, so that all the sides become parallel], they're the same...they don't intersect no more

Student A: Oh, A and B (length AB) and C and D (length CD) they are 79, and B and C (length BC) and A and D (length AD) are 84. So that means the opposite sides are the same on B and C and A and D...so we gotta say that the opposite sides on...sides on B and C and A and D are parallel...

They began by extending their figurative prototype of a trapezoid. They developed a relationship between the opposite sides being parallel and congruent to each other, prompting Student J to connect all of the shapes together in a hierarchical manner. This was an extension of Student J's relational prototypes. To make her point, she closed the trapezoid maker and then opened the rectangle maker.

Student J: Oh, do you get it now? ...you know how he said the squirrel [Earlier that day, their teacher discussed the hierarchical relationship between a squirrel and a mammal]...the rectangle can make into a square, it can make into a kite...some kind of kite. Trapezoid...so that means the rectangle is a square, and the square is the kite...

Student A: But we're not on rectangle.

Student J: Let's see what the trapezoid can make, since we're on trapezoid. [Student A closes the rectangle maker and then reopens the trapezoid maker.]

Student A: So we're on trapezoid.

Student J: Yeah, so let's see what this thing can make...can it make...are they (sides) even? No none of them are, Ok, see if you can make a square, then we can say the trapezoid makes a square, and the square can make a trapezoid, or the trapezoid can make a rectangle, the rectangle can make a square, and the square can make a kite.

This excerpt suggests that student began to informally explore the various relationships between square, trapezoid, rectangle and kite by morphing and manipulating the trapezoid maker. This illustrates the early stages of an action-based relational prototype of the square, trapezoid, rectangle and kite. Again, the students used the square and rectangle as referent object to help organize their relational understanding of the less familiar trapezoid and kite.

The students then consulted with one of the researchers to share their ideas. Notice the tension between the researcher using the term trapezoid maker and the students using the term trapezoid to describe the on screen geometric figure.

Student J: [To the researcher] We said the trapezoid can make a square, the square can make a rectangle, the rectangle can make a square, and the square can make a kind of kite.

Researcher: ...Let's use (trapezoid). Ok when you say this trapezoid, you're talking about this program right? OK, so that's the trapezoid maker.

Student J: Yeah, were talking about the trapezoid can make a square and a kind of kite out of the square. Like if you make a....

Researcher: ...Show me what you mean.

Student J: She's going to make a square....

Researcher: So the trapezoid maker can make a square, good.

Student J: The square can make a rectangle.

Researcher: Oh, I see what you are saying.

Student J: Out of the square we can make a rectangle, so that means what he was talking about the squirrel ...is these things can make different, this one can make more and more shapes, like squares.

Researcher: ... what you're saying is that the trapezoid maker can make a square...

Student J: The square can make a rectangle

Researcher: Ok...just so you know, you're still playing with the trapezoid maker...

Student J: Yeah.

Researcher: ...so the thing making the rectangle is actually the trapezoid maker.

Student J: Yeah, the trapezoid is the.... A square.

On the one hand the students wanted to share their findings. On the other hand, the researcher was trying to help the students distinguish between the shapes they were making and the tool they were using to make the shapes (i.e. - the trapezoid maker).

Student A: So probably what she is trying to get at is that the trapezoid and I think the kite they're like bendable...kind of like some people are double jointed and they can do more stuff kind of like that...

Student J: The trapezoid is a rectangle and a square and a kite

Researcher: Ok, it can make all those things...so what you are saying then is that a trapezoid maker can make a square...

Student J: So it is a square.

Researcher: Ah, not quite, it's the other way around, if a trapezoid maker can make square, then a square is a type of trapezoid

Student J: Yeah. That.

Researcher: That's what you want to say.

Student J: Cause a square can't make a trapezoid.

First, it appears that the students seemed to treat the shape makers as mathematical objects within themselves. This was in contrast to the researcher's view in which he treated them as on screen mathematical tools. It appears that the students were unable to make the distinction between trapezoid and trapezoid maker. However, this did not seem to limit their ability to construct meaningful relationships. In fact, their discursive practice gives evidence that their constructed notion of a trapezoid is very dynamic. Second, these dynamic geometric representations of the quadrilaterals allowed the students to discuss the hierarchical relationships in a form of actual reality (AR) discourse. Throughout the discussion, the two students characterize the trapezoid through the use of terminology like, "makes," "bendable," "double jointed," and "do more stuff." Of particular interest is the notion of "do more stuff" when referring to the kite and trapezoid maker. In the hierarchy, both shapes are right below the quadrilateral because their respective definitions are the most general and therefore, from a virtual reality (VR) point of view, encompass a greater variety of shapes. However, the students' characterization of doing "more stuff" in many ways is an AR description of the same hierarchical principle. The discourse is AR because the relational concept, a square is a type of trapezoid, is being mediated perceptually through the on screen figures. Furthermore, it appears that the students recognize the trapezoid's versatility over the square supported by student J's statement, "Cause a square can't make a trapezoid." The use of the square and rectangle as referent objects allowed students to begin a primitive construction of the quadrilateral hierarchy, supporting their understanding of trapezoids and kites.

### Discussion

Two important themes that emerged out of the data were the concurrent construction of figurative, operative and relational prototypes and the treatment of the shape makers as mathematical objects to construct hierarchical relationships between quadrilaterals. This was done without knowing the defining properties of each shape. In the video taped activity, the lessons first had the student explore shapes most familiar to themselves (squares and rectangles) and then progressed to less familiar shapes (trapezoid and kite). The purpose of the activity was to help the students learn the individual properties of each quadrilateral. In the first videotaped session, both students initially were focused on the specific properties of the quadrilaterals as they manipulated, morphed and dragged their dynamic shape makers focusing on the parallel sides, equal side lengths, and equal angle measures. In a sense they were constructing both figurative and operative prototypes. However, many of the figurative prototypes developed were general in nature. For example, when the students began their investigation of the parallelogram, they concluded that, unlike the rectangle, all the angles on a parallelogram were not equal to each other. The students never discussed specific angle relations like adjacent angles summing to 180 and opposite angles being congruent. This supports the holistic nature of prototypes in the development of a concept.

However, the lack of knowledge or understanding of specific quadrilateral properties did not prevent the students from concurrently constructing basic relational prototypes for these shapes.

Throughout the lessons, both students seemed to grasp onto the square and rectangle as referent shapes in which all other shapes were compared and evaluated. However, the students' comparison was done through their attempts to make one shape maker into several other shapes. This morphing activity with referent objects allowed the students to compare the properties of the various shapes. The students were in a sense, discursively constructing an understanding of each figure's side and angle properties (figurative prototypes) through this morphing process (operative and relational prototype). Our findings illustrate the concurrent construction of the students' figurative, operative and relational prototypes.

### Conclusion

Many traditional geometry curriculums see instruction as a construction of an axiomatic system through the use of definitions, postulates and theorems. In contrast, the dynamic geometric figures in Shape Makers (Battista, 1998) represent complex objects that embody a multitude of elements that make up that system. As a result, rather than a deductive construction of a geometric system, instruction takes the form of an inductive deconstruction of these very complex computer models. These semi-otic theories by Sfard (2000) and Doerfler (2000) helped us to explain the non-linear construction of abstract relational geometric concepts, and their operative and figurative counterparts.

## HIGH SCHOOL MATHEMATICS STUDENTS AND GEOMETRIC REASONING

Erdogan Halat  
Florida State University  
ehh0794@garnet.acns.fsu.edu

Leslie Aspinwall  
Florida State University  
aspinwal@coe.fsu.edu

This study compared the developmental reasoning stages of beginning and experienced geometry students with reference to a theoretical framework developed by Pierre van Hiele and Dina van Hiele-Geldof. The van Heile model has had an impact on the design of geometry instruction and curriculum as a way of overcoming difficulties teachers encounter in teaching high school geometry. Several results from the study are significant for mathematics education. We detected no statistically significant difference between the beginning and experienced geometry students' mean scores. There was a statistically significant gender difference among the experienced geometry students in the van Hiele levels. We were able to determine a difference in the van Hiele levels among the beginning geometry students and among experienced geometry students. The students' distribution seems not to be optimal for an efficient learning and teaching, since the properties of the levels suggest that two students who attempt to reason with each other but at different levels will experience difficulty in understanding each other.

This study compared the developmental reasoning stages of beginning and experienced geometry students with reference to a theoretical framework developed by van Hiele (e.g., Fuys, Geddes, & Tischler, 1988; Usiskin, 1982). In particular, the study attempted to answer the following questions: (1) What differences exist according to the van Hiele levels between beginning geometry students and experienced geometry students? (2) What is the significance of gender among the experienced geometry students in the van Hiele levels? (3) What generalizations can be made among low van Hiele level students, high van Hiele level students, beginning students, and experienced students?

The study was based on two theoretical positions. The first is a pedagogical orientation that acknowledges the importance of teachers' knowledge of student cognitions (e.g., Carpenter, Fennema, Peterson, Chiang, & Loef, 1989; Shulman, 1989). The second is a cognitive framework (cf. Usiskin, 1982) developed by Pierre van Hiele and Dina van Hiele-Geldof that captures the manifold nature of students' geometric reasoning and, in particular, identifies five developmental levels. The cognitive framework was used to generate assessment protocols and evaluation tasks and to evaluate the impact of instruction on development stages of students' geometric thinking. The van Heile model has had an impact on the design of geometry instruction and curriculum as a way of overcoming difficulties teachers encounter in teaching high school geometry (e.g., Hoffer, 1981; Usiskin, 1982). Pierre van Hiele and Dina van

Hiele-Geldof proposed their model in 1957 and refined it between 1957 and 1986. The model delineates five development stages experienced by all learners of geometry: visualization or recognition (level-0), analysis (level-I), abstraction (informal deduction) (level-II), deduction (level-III), and rigor or axiomatic (level-IV).

One of the first lines of research on the model was reported by Wirszup in 1976 (as cited in Mayberry, 1983), and eventually attracted educators' attention. Usiskin (1982) worked on the validity of the van Hiele levels. He confirmed the validity of the first four levels in geometry learning. In 1986, Burger and Shaughnessy focused on descriptions and characteristics of the van Hiele levels. Fuys, Geddes and Tischler (1988) examined the effects of instruction on a student's predominant van Hiele level. Some of these researchers confirmed the validity of levels and investigated students' behavior on tasks while others studied evaluation and assessment of the geometric ability of students as a function of the van Hiele levels. Mayberry (1983) reported that her findings with 19 undergraduate elementary teachers supported the hierarchical aspect of the theory, but she did not support the idea that an individual showed the same level of thinking in all areas of geometry. Gutierrez, Jaime & Fortnuy (1991) replicated these results with preservice teachers in Spain for levels I-IV.

### **Methods of Inquiry**

We defined beginning geometry students as those who have just begun their study of high school geometry. Experienced geometry students are algebra-II students who had already completed the study of geometry during the past year. The criterion for high van Hiele level was determined to be level III (deduction) or level-IV (rigor or axiomatic); otherwise the student was considered to be at a low van Hiele level. The subjects for this study were four classes of secondary school mathematics students. Two classes were taking high school geometry (beginning geometry students) and two classes were taking algebra-II (experienced geometry students). Those who were enrolled in algebra-II at the time of the study took geometry the previous year. Algebra-II is the next course following geometry in the high school mathematics sequence. The total number of subjects for the study was 100 students, 53 from geometry classes and 47 from algebra-II classes.

We used two types of test instruments, the Entering Geometry Test (EGT) and the van Hiele Geometry Test (VHGT), taken from Usiskin's Cognitive Development and Achievement in Secondary School Geometry Project (1982) used by his permission. The EGT is a beginning test consisting of 20 multiple-choice geometry questions for 25 minutes. The VHGT is an advanced test containing 25 multiple-choice geometry questions for 45 minutes. It is designed for testing and evaluating the students' geometric reasoning ability rather than computation. In particular, the VHGT is designed to identify an individual's van Hiele level of geometric thought and to compare differences among low and high van Heile levels of students and beginning and experienced students.

Both tests – first the EGT and next the VHGT – were administrated by the researcher during two arranged sessions. After the second test, the researcher selected twelve volunteers for individual interviews. Interview items, from the written tests, were decided and selected after the administration of the tests: two questions from EGT and three questions from VHGT, depending on the students' responses to the questions. The aim of the interviews was to see how students perform orally in an attempt to confirm their level of performance on the written test and to validate written test results. Two characteristics, teachers' personal judgment of students' potential and the results of the VHGT, played an important role in the selection of volunteer students for the 30-minute individual interviews.

The sessions were audiotaped to create a transcript of each interviewee's responses. The data sets are the responses from the students' answer sheets and the interview transcripts. The responses of students and the interview transcripts were evaluated in light of the van Hiele theory. In the analysis of scores from the EGT and the VHGT, a one-way and a two-way analysis of variance were used to confirm significance of differences found.

### Results

The data from the study indicated several results that are significant for mathematics education. Although the beginning geometry groups' mean scores appeared numerically higher than the experienced geometry groups' mean, there was no statistically significant difference between the two. There was a statistically significant gender difference among the experienced geometry students in the van Hiele levels, and gender had an effect on scores. The male students' scores were significantly statistically higher than the female students' scores on the VHGT test. We were able to determine a difference in the van Hiele levels among the beginning geometry students and a difference in the van Hiele levels among experienced geometry students. The students' distribution seems not to be optimal for an efficient learning and teaching, since the properties of the levels suggest that two students who attempt to reason with each other but at different levels will experience difficulty in understanding each other.

## **PROSPECTIVE MATHEMATICS TEACHERS' LEARNING IN GEOMETRY – THE BEGINNING OF A LONGITUDINAL STUDY ON TEACHER EDUCATION**

Mikael Holmquist  
Göteborg University, Sweden  
Mikael.Holmquist@ped.gu.se

The way mathematics teachers understand geometrical concepts influences their teaching and consequently what their pupils might learn. Every semester since the spring of 1999, prospective mathematics teachers at Göteborg University have responded to a questionnaire that address questions regarding how the students conceive concepts in geometry. The written answers are analyzed with respect to concept images and the way the students make use of their concept images and the mathematical definition of certain concepts. As a base for an extended analysis some other qualitative aspects are identified.

### **Introduction**

When discussing teacher qualifications in mathematics and education of future teachers in mathematics, the branch of geometry is of course only a small part of the science mathematics. Nevertheless, there exist reasons and arguments for why we should try to observe and educate competencies for teachers in mathematics with geometry in focus (Niss, 1998). This will include teachers' views and knowledge of geometry as a mathematical topic as well as the kinds of knowledge and views that they should have of the processes of learning geometry.

In Sweden, as well as in other countries, geometry was an essential part of school mathematics during the period from the middle of the 1800-century to the end of the 1950's. One interpretation of this fact is that geometry and especially the Euclidean plane geometry was removed by the introduction of the "new mathematics". Later on, there have been discussions (Kapadia, 1985) whether the loss of geometry in the school mathematics may have caused a drawback regarding student's understanding of general concepts or not. As a result, geometry and measuring has a more prominent position in the mathematics syllabuses for the Swedish school today (Skolverket, 2000a, 2000b). The programs for teacher education seem to have followed the same patterns, only with a slight displacement in time. Despite this, teachers of today are expected to fulfill the national curriculum and ensure that their students reach proficiency in these areas.

### **The Study**

At Göteborg University, students preparing to become teachers of mathematics and natural science for Grades 4 to 9 or for the gymnasium (Grades 10 to 12) take courses in mathematics that are offered by either the department of mathematics or by the department of mathematics education. One such 5-credit point (5 weeks full-

time study) course is called *Geometry and Mathematical Modeling*, in which there is a strong emphasis on the use of graphing calculators and a variety of software, both from a mathematical and a didactical perspective. The students come to the course after having taken different courses in mathematics where the content vary over time. At present time the students come with courses in number theory, Euclidian geometry, linear algebra, and real analysis, which approximately correspond to 30 weeks of full time studies. Beginning in the spring of 1999, the students who came to the course were given a questionnaire, which address questions regarding how the students conceive concepts in geometry.

This study is based on written responses that have been collected from all the entrance questionnaires on geometry administered during the last 7 semesters, including the Spring 2002 course. The students were given the questionnaire the first day of the course and there was no time limit for them working on it, although up to now no student has used more than 80 minutes. At present, 197 students have responded to the questionnaire. The issue in focus is the identification of the prospective teachers' concept images and the way they make use of their concept images and the mathematical definition of certain concepts, geometrical concepts that they will find central when they begin their professional life as mathematics teachers. The two elements, concept image and concept definition relates to the work done by Hershkowitz and Vinner (Hershkowitz, 1990) and are used as a framework for the analysis of the students' written responses. The starting-point for the analysis is the interpretations of what the students' have described in their written answers to the questionnaire (Patton, 1990). The way the questions in the questionnaire are formulated is indicating that the geometrical meaning of the concepts is in focus.

The selection of questions in the questionnaire are closely related to the national curriculum for the Swedish comprehensive school and for the Swedish Gymnasium (Skolverket, 2000a, 2000b), to analysis of common text books that are used in Swedish schools, and to the kind of geometrical concepts that are used in national tests. The students were asked to give an explanation to the following five concepts: *diagonal*, *congruence*, *parabola*, *rhomb*, and *cycloid*. Beside this, the students responded to two different questions regarding the differences of construction and drawing in plane geometry. Different responses were classified according to the critical attributes of the actual concept used by the students, but the reasons for the differences were not analyzed.

### Findings and Conclusions

Most of the findings correspond to these described by Hershkowitz and Vinner (Hershkowitz, 1990). The concept image expressed by a student is often only part of or may not coincide at all with the definition of the corresponding mathematical concept. The prototype phenomenon was also observed frequently in the students' descriptions, which means that each concept has one ore more prototypical examples

that are attained first and therefore exist in the concept image of most students in the study. Besides this there are results that could form the basis of an extension of the model used for analysis. There are reasons to separate the students' answers in a qualitative aspect, not only in 'correct' or 'non correct'. This will mean if a description of a certain concept is bounding its meaning to a specific situation (see the response from *student 1* below) or if the description will allow generalizations (see the response from *student 2* below).

Explain in short terms the following geometrical concepts; please use both pictures and words. Even if your belief about the concept is vague, we appreciate if you as clear as possible will try to give an explanation.

### *Diagonal*

Student 1: A diagonal is dividing all rectangles, squares, rhombus, parallelogram in two equal parts.

Student 2: A straight line between two corners in an object with  $n$  corners,  $n \geq 4$ ,  $n \in \mathbb{N}$ . Note. Not between two adjacent corners.

This aspect is of particular importance when a teacher use his or hers explanations to meet and support students in their learning of geometrical concepts. With this in mind, another key aspect when analyzing the data is the students' use of different languages, a more formal or an everyday language. They also use metaphors, like a description of what to do to get an impression of the meaning of a certain concept.

Despite the fact that several students demonstrate serious lack of concepts in the questionnaire, quite a few of them manage to illustrate acceptable mathematical reasoning during the final examination. One important tool for teaching and learning geometrical concepts in the course was The Geometer's Sketchpad (Jackiw, 1995). The students' work with the software was complemented with seminars and discussions regarding computer supported learning in geometry reported by for example Laborde (2001).

The results emerging from the described study will form the basis for deeper studies of what these prospective mathematics teachers learned in geometry and how their understanding of the theoretical mathematical content later on was expressed in their teacher practice.

## **THE BENJAMIN BANNEKER PROJECT: A STUDY OF AFRICAN AMERICAN CHILDREN'S PROBLEM SOLVING**

Jacqueline Leonard, James Davis, Patrick Spearman, & Smita Guha  
Temple University

The Benjamin Banneker Project responds to the achievement gap in mathematics and science (Irvine & Armento, 2001) and the digital divide in technology (Wenglinsky, 1998) that continue to exist between mainstream and African American students. The purpose of this one-year project is to develop and field-test computer software that uses intelligent computer-assisted instruction (ICAI) to help third-grade African American children solve culturally relevant mathematics and science problems. However, developing software that is culturally relevant is exploratory and somewhat risky because such software is initially very expensive to develop, and it targets only a specific group of students. The rationale for selecting third graders is that differences in minority students' motivation and achievement in mathematics begin to occur around fourth grade (Ladson-Billings, 1997); the rationale for selecting African American students is that they have the lowest scores in science and mathematics (Tate, 1997). Yet, if the needs of these children are met by intelligent tutoring, then ICAI has the potential to impact on the learning of all children.

The goals of this project are to influence the classroom environment as well as the instruction of African American students as teachers are encouraged to use technology as an emerging curriculum rather than as a reward or only to supplement traditional instruction. Furthermore, rather than merely being receivers of digital information, the students would be able to interact with the computer, which will respond with cues to help students solve culturally relevant mathematics and science problems. Our study takes place in two charter schools in Philadelphia: Alliance for Progress Charter School and Harambee Institute of Science and Technology Charter School.

Integrating technology into the school curriculum remains a daunting challenge, despite the fact that high-tech computer workstations are commonplace in most teachers' classrooms (Ertmer, Addison, Lane, Ross, & Woods, 1999). However, teachers participating in this project have learned to use the software and how to become more culturally responsive to their students. Thus, teachers have learned how to become cultural brokers in the classroom (Aikenhead, 1996) as well as how to run the software program and monitor student progress. In addition, the teachers have attended ongoing inquiry group sessions to learn how to integrate computers more fully in the classroom and how to help children develop their own word problems. Teacher activities focused on using technology and pedagogy to help African American children to become proficient in solving culturally relevant word problems in order to increase their persistence and repertoire of problem solving strategies for use in other contexts (cultural brokering).

During this poster presentation the authors will present the software that has been developed to date. The software is unique in that mathematics and science problems will be embedded within the theme of the Underground Railroad. The main character, Moses, travels from a plantation in Bucks County, Maryland, to freedom in Philadelphia, Pennsylvania, along the Underground Railroad. His journey involves both mathematical and scientific decision-making as he encounters obstacles such as poison ivy, wild animals, and general survival issues along the way. Moses uses the stars to guide him North and has to travel an average of 8 miles per day to get to Philadelphia before his rations run out. This software is patterned after the Oregon Trail and is being pilot tested with third-grade African American students. Data from teacher professional development workshops and student interactions with the media as well as the problems and problem solving strategies will be presented along.

## INITIATING PROBLEM POSING THROUGH EXPLORATION WITH SKETCHPAD

Nathalie M. Sinclair  
Simon Fraser University  
nathsinc@educ.queensu.ca

Problem posing can be seen as a necessary, or at least desirable, precursor to problem solving. As a creative, personal form of mathematical thinking, problem posing is an activity that is often difficult for teachers and students to engage in—where to start? Where to go? How to get there? Based on both theoretical and empirical inquiry, this poster presentation proposes that “mathematical play” is an essential precursor to problem posing and can be stimulated in learning environments that explicitly enable aesthetic engagement and exploration.

Problem posing is an essential component of the professional mathematician’s practice and has received increasing interest among mathematics educators. However, despite the many strategies offered by Brown and Walter (1983), researchers have found it difficult to elicit problem posing behavior in the classroom (Silver, 1994). This may be due to students’ limited exposure to varied problem situations in the classroom, as well as to the disconnect between students’ informal, intuitive mathematical knowledge and their formal “school math” knowledge. Furthermore, in order to pose a problem, one must perceive a situation as being problematic, that is, as surprising, strange, or unexpected enough to initiate wondering and questioning (Dewey, 1938). Therefore, researchers such as Hawkins (2000) have suggested that problem posing can only occur after a period of exploration during which an inquirer gets acquainted with a mathematical situation. Often, the pedagogical challenge is to find ways in which to engage students in meaningful (to them) and relevant (to the curriculum) exploration.

This poster presentation reports on three examples of mathematical situations given to a small group of middle school students using The Geometer’s Sketchpad (Jackiw, 1991) that succeeded in fostering exploration and, in turn, problem posing. I compare these three examples with the types of tasks more commonly proposed to students using DG software, such as “discovery problems” or “guided inquiry problems” and highlight the often implicit pedagogical theories and intentions that influence students’ attitude and behavior.

The first example was inspired by Walter’s (2001) description of her own process of exploring and mathematizing Theo van Doesburg’s *Arithmetic Composition I*. The second example involves Archimedean tessellations and the third star polygons. The two latter examples are common topics in textbooks and other resource materials, but were designed and presented to students as “guided inquiry” as opposed to “discovery problems.” Based on my observations of students’ interactions with Sketchpad, on analyses of their activities, and on follow-up interviews, I identify some of the

mathematical ideas, Sketchpad abilities, and habits of mind that were initiated and developed throughout their work. I pay particular attention to: the motivational characteristics of the situations, that is, those that elicited the attention of the students and thus provoked subsequent constructions, actions and conjectures; the way in which Sketchpad supported student exploration and problem posing; the evaluative characteristics of the situations, that is, those that initiated the types of reflections and judgements that lead to student evaluation of the significance or interest of a particular problem or solution.

# **CONCEPTUAL UNDERSTANDING AND COMPUTATIONAL EFFICIENCY: CHILDREN'S STRATEGIES FOR MULTIPLYING MULTIDIGIT NUMBERS**

Jae Meen Baek  
Arizona State University  
jae.baek@asu.edu

This paper aims to examine children's conceptual understanding and computational efficiency in the domain of multidigit multiplication. In this study, children's invented strategies for multiplying multidigit numbers were used as a window to explore their understanding of multiplication and its underpinning properties. Fifty-eight children in grades 4 and 5 were individually interviewed with multidigit multiplication problems in equal grouping context. Based on the use of groups, knowledge of place value, and use of the properties of multiplication, children's invented strategies were classified into several categories and children were clustered into strategy groups based on their primary choice of strategies. The analyses of invented strategies for multiplication demonstrate sophistication of children's understanding of the operation and the distributive and associative properties and limited understanding of the commutative property. In addition, the findings of this study provide empirical evidence of the interconnectedness of children's conceptual understanding of multiplication and computational proficiency.

Recent reform efforts in mathematics education hypothesized the interdependency of the conceptual understanding and computational proficiency, and research in cognitive science provides a general support for the interdependency (Kilpatrick, Swafford, & Findell, 2001; Wu, 1999). However, there has been little empirical evidence that showed how these two strands played a role in children's problem solving activities. This paper aims to examine children's conceptual understanding and computational efficiency in the domain of multidigit multiplication. In this study, children's invented strategies for multiplying multidigit numbers are used as a window to explore their conceptions of multiplication and understanding of underpinning concepts and properties. This window allows investigation of what the invention may afford or limit with the respect of children's understanding and computational skills.

## **Theoretical Background**

### **Invented Strategies and Conceptual Understanding**

A significant body of research has shown that children can construct solution strategies for addition and subtraction without explicit instruction in specific procedures (Carpenter, Ansell, Franke, Fennema, & Weisbeck, 1993; Carraher, Carraher, & Schliemann, 1987; Cobb & Wheatley, 1988; Hiebert & Wearne, 1996; Olivier, Murray, & Human, 1990; Saxe, 1988). Researchers focused on children's invented strategies based on a hypothesis that invention can play a central role in helping children develop conceptual understanding of numbers and operations. Carpenter and Lehrer (1999)

provided a theoretical framework to define what it means to understand mathematics and discussed how the process of inventing alternative strategies and articulating underlying reasoning could enhance children's conceptual understanding. They also discussed the pitfalls of learning mathematical procedures without understanding and when children learn skills in the relation to developing a conceptual understanding from the beginning of schooling, mastery of skills is facilitated as well as understanding.

A longitudinal study by Carpenter and his colleagues (Carpenter, Franke, Jacobs, Fennema, & Empson, 1998) provided empirical evidence that supports the proposition of the relationship of invented strategies and children's development of conceptual understanding. They traced the development of children's solution procedures for addition and subtraction for three years and found that children in grades 1-3 who used invented strategies before they learned standard algorithms demonstrated better understanding of place value concept and were more successful in transferring their knowledge to new situations than were students who initially learned standard algorithms. These results are consistent with the theoretical perspective that the development of conceptual understanding before mastery of skills enhances children's mathematical learning (Hibert & Carpenter, 1992).

In this paper, I extend this line of research to the domain of multidigit multiplication and examine conceptual understanding that children develop through the process of constructing alternative strategies in a more complex domain of multidigit multiplication. Furthermore, I investigate children's development of computational procedures and its connection to their conceptual understanding of multidigit multiplication.

### **Children's Invented Strategies for Multiplication**

An understanding of multiplication plays a central role to children's reasoning of multiplicative structure. Sound understanding of multiplication enables children better understanding of division, ratio, proportion, and rational numbers. In spite of the importance of the concept and calls for more research in this domain, most research on children's learning of multiplication has focused on students' misconceptions of multiplication (Fischbein, Deri, Nello, & Marino, 1985; Greer, 1988; Mangan, 1986) and research on children's understanding has been relatively limited (Kilpatrick, Swafford, & Findell, 2001).

Several studies investigated children's invented strategies for single-digit multiplication problems (Anghileri, 1989; Carpenter et al., 1993; Heege, 1985; Kouba, 1989). Anghileri, Carpenter et al., and Kouba illustrated strategies constructed by children as young as five or six and the strategies in the studies showed that young children's invented strategies develop from direct representation of the problems with physical materials to several forms of counting strategies. Heege identified six different strategies that children in grades 2-6 constructed: doubling, halving, increasing a familiar product by adding the multiplicand once, and decreasing a familiar fact by subtracting the multiplicand once.

Recent research showed that children can construct a wide range of sophisticated strategies for multiplying multidigit numbers (Ambrose, Baek, & Carpenter, in press; Baek, 1998; Kamii, 1994; Lampert, 1986). Teaching experiments by Kamii and Lampert in a third- and a fourth-grade classes illustrated that children can develop partitioning strategies using intuitive understanding of the distributive or associative properties. In my previous studies (Ambrose, Baek, & Carpenter, in press; Baek, 1998), I attempted to characterize the nature of children's invented strategies by analyzing the strategies based on underpinning mathematical concepts and properties of the strategies. I constructed a comprehensive taxonomy by reconstructing the classification schemes of Heege (1985) and Kamii (1994). However, the data was not sufficient to generate firm conclusions about the development of children's understanding of multidigit multiplication (Kilpatrick, Swafford, & Findell, 2001). In this study, the classification scheme is further refined by comprehensive analyses of underpinning mathematical concepts and properties of multiplication, and the relationship of the level of sophistication of invented strategies and the level of computational efficiency is investigated.

## **Methods**

### **Subjects**

The students in this study consisted of 58 students in 3 fourth- and fifth- multi-graded classes at one school. Thirty-two of the 58 students were in fourth grade and the other 32 were in fifth grade. All 32 fourth graders and 7 of the 26 fifth graders were in traditional classroom in the previous year. About 70% of the students who participated in the study were White and about 15% of the students were on free or reduced lunch.

### **Classroom Instruction**

Classroom instruction is potentially an influential factor on children's inclination and ability to generate invented strategies. The three teachers whose children were interviewed in this study had participated in a research program designed to focus on helping teachers understand children's mathematical thinking in primary grades (Carpenter, Fennema, & Franke, 1996). At the time of the study all three teachers had participated in the program for more than 7 years and shared the perspective that children could invent procedures to solve problems and instructional decisions should be made based on children's thinking, so that teaching can support children's understanding of mathematics more effectively. The teachers routinely provided problems in real world context and built a classroom norm that children construct their own strategies and discuss them. The standard algorithms were not taught in the classes. When a child who learned them at home or previous year used the algorithm, it was not accepted as an appropriate solution unless the child could explain why the algorithm worked.

## Interviews

Clinical individual interviews with fifth graders were conducted in November and December, and the interviews with fourth graders were conducted in the following March through early May. I interviewed all students and each interview lasted between 30 to 90 minutes. To encourage children to use abstract strategies, only paper and pencil were readily available during the interview. After the child gave an answer, the interviewer asked the child how he or she solved the problem. I recorded detailed notes on each child's solution strategies. All the interviews were audiotaped, and child's written work was collected.

The interview tasks assess (a) students' knowledge of place value concepts, (b) their invented strategies for multidigit multiplication problems, and (c) their abilities to use specific invented strategies. The problems for place value assessment consisted of two word problems involving multiplication and division problems with 10 objects in each group. In the second set of the tasks, eight multiplication problems in equal grouping context were asked (for different types of multiplication problems, see Greer, 1992). Children were classified as demonstrating knowledge of base-10 number concepts if both of their responses were coded as demonstrating place value knowledge. The multiplication problems to assess children's invented strategies were chosen to investigate how the size and role of the multiplier and multiplicand influence children's choice of strategies. Two problems constructed with one- and two-digit numbers, four problems with two-digit numbers, and two problems with two- and three-digit numbers. The third set of the tasks assessed children's understanding of three specific strategies: (a) partitioning both numbers into decade numbers strategy, (b) compensating strategy, and (c) commutative strategy. Children were shown how a hypothetical child used each strategy, and were asked to explain and replicate the strategy for a different problem.

## Analyses

Children's responses were initially coded whether the answer was correct or not. Strategies that lead to an incorrect answer were analyzed if the strategy would have resulted in a correct answer if the solution was carried out without any calculation errors. If the calculation errors were simple counting, adding, or recall fact errors, and two or fewer errors were made for a single problem, the strategy was coded valid. Strategies for multiplication problems initially coded in predetermined categories (Ambrose, Baek, & Carpenter, in press; Baek, 1998). On the basis of interview notes and audiotaped protocols of each child's explanations, new categories were constructed or the existing categories were modified to capture mathematical differences between strategies. Descriptions of each of these strategy types are provided in results.

After the strategies for all eight multiplication problems were classified, each child's most prevalent strategy was identified and children were clustered into strategy

groups. Because children used different kinds of strategies for smaller numbers, strategies for problems with two-digit numbers or larger were given more focus for clustering. A child who solved 5 or more of 6 problems with larger numbers correctly was classified in a specific strategy group if he or she used the type of strategy for four or more problems. A child who solved 4 of 6 problems correctly had to solve more than three problems using a specific strategy to be classified in that strategy group. A child who solved three problems or fewer had to use a single strategy for all problems.

### **Results**

Children in this study invented a wide range of strategies for multiplication problems. The invented strategies showed different levels of children's understanding of units, place value, and properties of multiplication. The problem context seemed to help children understand the operation of multiplication and construct meaningful computational procedures. Many children constructed reasonably efficient strategies using their intuitive understanding of distributive and associative properties, and were able to justify the solution procedures using the problem contexts. By the same token, the problem situations seemed to influence children's strategies in that they assigned different roles to the multiplier and multiplicand. Most children did not use the commutative property even when switching the roles of the two factors would have made the calculation procedure easier.

#### **Children's Invented Strategies for Multidigit Multiplication**

I classified children's strategies into four main categories: (a) direct modeling, (b) adding/ doubling, (c) partitioning, and (d) compensating. The strategies in the adding/ doubling category and the partitioning category were further classified into a number of subcategories. Children who used direct modeling strategies represented the number of groups and the number of objects in each group. The adding and doubling strategies were more abstract than direct modeling. Those strategies are based on repeated addition, which some children shortened by doubling. When children used the partitioning strategies, many split the multiplier into smaller numbers and created multiple sub-problems that were easier to deal with. This procedure allowed the children to reduce the complexity of the problem and to use multiplication facts that they already knew. Children who used compensating strategies adjusted the multiplicand or/ and multiplier based on special characteristics of the number combination to make the calculation easier. Children then made corresponding adjustments later if necessary. Only a few students used the direct modeling strategy. Students who used the direct modeling strategy represented each of the groups with tally marks or other drawings and counted the total number of objects. In following sections, each of the invented strategies is described and illustrated.

### Partitioning both numbers into decade numbers

More sophisticated strategies entailed partitioning both the multiplier and multiplicand. In the following example, Sean partitioned both numbers to solve the problem, 43 boxes with 24 cards per box (Figure 6). Sean set up a table with 4 and 3 on the top and said that he kept 20 and 4 at the side of the table in his head. He multiplied 20 by 40 and by 3, and 4 by 40 and by 3. It was an efficient in a way that did not involve any addition procedures to generate four partial products by taking advantage of Sean's knowledge of number facts. Whereas children who partitioned only the multiplier often explained their solution procedures using references in the word problem context, children who partitioned both number never specifically related solution procedures to the problem context.

$$\begin{array}{r|l}
 4 & 3 \\
 \hline
 800 & 60 = 860 \\
 160 & 12 = 172 \\
 \hline
 & 1032
 \end{array}$$

Figure 6. Sean's Both Number Partitioning strategy for the problem, 43 boxes with 24 cards per box.

### Compensating

A few children in the study adjusted one or both of the factors in the problem on the basis of the special characteristics of the number combinations. Then they made corresponding adjustments later to figure out the final product. Most children who used compensating strategies rounded one of the factors up to the nearest decade number in order to simplify their calculation by taking advantage of their knowledge of place value. In the following example (Figure 7), Sarah used the strategy, saying that she knew 47 was very close to 50 and a half of  $100 \times 34$  would get her  $50 \times 34$ . She knew  $100 \times 34$  was 3400 and calculated a half of it, saying "I know a half of 3000 is 1500 and a half of 400 is 200. 1500 and 200 is 1700." Then Sarah calculated  $34 \times 3$  at the bottom, saying "I know  $30 \times 3$  is 90 and  $4 \times 3$  is 12. So 90 plus 12 is 102." She figured out the final answer by subtracting the three groups of 34s from 50 groups of 34s. Sarah's compensating strategy demonstrated her flexible number and operation sense that capitalized on her knowledge of place value. Sarah used her implicit knowledge of the associative and distributive properties to round up the multiplier to the decade number and then to the hundred.

$$\begin{array}{l}
 100 \times 34 \rightarrow 3400 \div 2 \\
 \rightarrow 1,700 - 102 \rightarrow 1,598 \\
 34 \times 3 \rightarrow 102
 \end{array}$$

Figure 7. Sarah's Compensating strategy for the problem, 47 children pay \$34 each.

### Clustering Children into Primary Strategy Groups

Next I describe students' strategy groups constructed based on the dominant invented strategies that students' used for multiplication problems. The clustering

process revealed that children's use of strategies was remarkably consistent; out of 54 children, 35 children used a single strategy for the problems involving two-digit numbers or larger; 15 children used two strategies; only 4 children used more than 3 strategies.

Table 1 shows the number of children in each of strategy groups, the number of children who demonstrated place value understanding, the average number of prob-

b. Numbers which fall between two strategy groups represent children who used both two strategies.

lems solved by children in each group, and the average number of specific strategies replicated by children in each group. The construction of clusters reveals that there are tight relationships between the type of primary strategy, the number of problems that children solved successfully, their place value knowledge, and the number of specific strategies that children could replicate.

With an exception of the complex doubling group, the clusters show that the level of abstraction of the strategies is closely related to the number of problems that children could solve. Children in the direct modeling, adding, and doubling group could not solve any problems beyond one-digit times two-digit numbers. Children in the non-decade number group found that the multiplication problems involving two-digit and three-digit numbers were too difficult for them to solve. It seemed that the size of units that children in the non-decade number partitioning group created was relatively small (less than 6) and it required many steps to solve a problem involving large number of groups. Children who partitioned one of the factors into tens and ones and used addition procedures to figure out the partial product were very successful solving all problems involving two-digit numbers and a problem involving a two-digit number times a three-digit number. However, they could not solve a problem involving a three-digit number times a two-digit number. Children who consistently partitioned one of the factors into decade numbers and utilized the place value structure in our number system were highly successful solving all the problems. In this group, children who alternatively partitioned the multiplier and multiplicand appeared to be more successful solving the multiplication problems than the children who always partitioned the multiplier only. In spite the fact that a both number partitioning strategy requires more an abstract translation of problem situations, two children who primarily used this kind of strategy was not as successful as children who mainly used single number partitioning strategies. They could not figure out the product of decade numbers or generated only two partial products when four partial products were necessary (*buggy algorithm*).

Children in the groups of direct modeling/adding/doubling and non-decade number partitioning did not demonstrate the place value knowledge in the interview tasks. Children in the group of decade number partitioning with adding showed that most of them knew the product of  $b$  groups of 10 but they needed to go through an addition procedure to figure out 10 groups of  $b$ . It shows that knowledge of  $b$  groups of 10 objects does not easily translate to 10 groups of  $b$  objects for children.

Children's understanding of specific strategies was also closely related to their primary strategy. Children in the decade number partitioning strategy with place value knowledge group could replicate more specific strategies than children in other groups. It showed that these children possessed highly fluent computational skills to solve the problems as well as conceptual understanding to make sense of strategies that they had not constructed. Also these replication tasks shed a light on a couple of

unexpected findings. First, a number of students who could explain the both number partitioning strategy failed to replicate it because they could not correctly multiply two decade numbers, such as  $30 \times 40$ . Many children answered that  $30 \times 40$  was 120 or 112. Second, a couple of children in the non-decade number partitioning group understood the mechanism of the compensating strategy but failed to replicate the strategy because their computational skills could not take advantage of the multiple of a decade number.

## **Discussion**

### **Invented Strategies and Understanding of Multidigit Multiplication**

The results of this study support the hypothesis that invention plays a significant role in children's development of conceptual understanding. Children employed fundamental principles of multiplication, underlying concepts of base-ten numbers, and their implicit understanding of the distributive and associative properties to derive invented strategies. Children with a high level of partitioning strategies showed that they are not only fluent at decomposing, keeping track of the number of groups that they were calculating, and recomposing the partial products to generate the final answer, but also flexible in applying and extending their knowledge to make sense of new strategies and to use them for themselves.

### **Computational Efficiency**

Although children's invented strategies indicate their deep understanding of multiplication, they revealed children's limited knowledge in two specific areas. First, a significant number of children knew the product of multiples of 10 but used addition procedures to calculate the product of 10 groups of objects. The difficulty with this task is also related to their understanding of commutativity.

Second, a small number of children failed to carry out both number partitioning because their knowledge was limited in calculating a product of two decade numbers, such as  $30 \times 40$ . It was unexpected that children with this level of abstraction say  $30 \times 40 = 120$  because you have to add a zero. One of the teachers of the students speculated that children might have had difficulty because they thought that there would be easy rule that they could apply in order to deal with zeroes and they were less inclined to use partitioning strategies.

These difficulties seem to be due lack of explicit experiences of the tasks. Children in the study spent a great deal of time constructing meaningful strategies for word problems. The specific knowledge to carry out particular strategies was not necessarily a focus of the instruction. The results of the study suggest that computation efficiency of these children would greatly improve with specific knowledge of multiplying 10 and decade numbers.

In conclusion, the findings of this research support the hypothesis of interdependency of conceptual understanding and computational skills and call for more research on children's strategies to inform research and practice about related concepts and skills.

# **FACTORS AFFECTING NINTH GRADE TURKISH STUDENTS' SELF-CONFIDENCE IN LEARNING MATHEMATICS**

**Safure Bulut**

Middle East Technical University  
sbulut@metu.edu.tr

**Yusuf Koc**

Indiana University - Bloomington  
ykoc@indiana.edu

In this study, we will present the findings of a research study on factors affecting ninth grade Turkish students' self-confidence in learning mathematics. 841 ninth- grade students (374 females and 467 males) participated in the study. The data was collected through conducting the Mathematics Achievement Test (MAch) developed by Bulut and Tag (2000). We also used the scales that Bulut and Tag (2000) adopted from Fennema and Sherman scales: Self-Confidence in Learning Mathematics (Con) Scale, Attitude Toward Success in Mathematics (AtSc) Scale, Mathematics Anxiety (Anx) Scale, Father (FcSt) Scale, Mother (McSt) Scale, and Teacher (TcSt) Scale. We can predict the student's self-confidence in learning mathematics by using above equation included MAch, AtSc, Anx, FcSt, McSt and TcSt. In other words, students' self-confidence in learning mathematics is affected by their mathematics achievement, attitude toward success in mathematics, mathematic anxiety and perceived attitude of father, mother, and teacher toward one as a learner of mathematics.

The main goal of this study is to examine the relationship between 9th grade Turkish students' mathematics achievement, attitude toward success in mathematics, mathematics anxiety, gender, perceived parent and teacher characteristics related to student, and their self-confidence in learning mathematics by using correlational research methods.

## **Perspectives/Theoretical Framework**

Confidence in learning mathematics refers to confidence in one's ability to learn and perform well on mathematical tasks (Fennema & Sherman, 1976). Armstrong (1981) stated a relatively strong relationship between confidence in learning mathematics and achievement in mathematics. In particular, students who are sure of their ability in mathematics will probably choose tasks involving mathematics more often and persist longer than those who are not sure they will succeed. Confidence in learning mathematics is also reflected in course taking and career aspirations in quantitative fields. Consequently, research studies about confidence in learning mathematics indicate the importance of this variable in relation to student achievement.

According to a meta-analysis, there is a significant gender difference in mathematics self-confidence (Hyde, Fennema, Frost & Hopp, 1990). Researchers have identified parental and societal attitudes as being influential in making girls internalize the feeling that they are inferior to boys in mathematics (Parsons, Kaczala & Meece, 1982). Since previous research provides evidences that gender differences account for self-confidence in learning mathematics, in this proposal, gender is considered as a predictor variable.

Teacher's attitudes and effectiveness in teaching mathematics are viewed as prime determiners of students' attitudes and performance in subject matter (Carter & Norwood, 1997). The students' family background is also influential even in learning mathematics, which may appear to be learned exclusively in school (Wang, Wildman & Calhoun, 1996). Thus, in the present study, perceived parent and teacher characteristics related to student are considered as key variables to predict students' self-confidence in learning mathematics. These variables refer to students' perception of their parents' and teacher's attitudes toward them as learners of mathematics. They also include parents' and teachers' interest, encouragement, and confidence in the student's ability (Fennema & Sherman, 1976).

Fennema and Sherman (1976) stated that attitude toward success in mathematics refers to students' anticipation about positive or negative consequences as a result of success in mathematics. They also explained that mathematics anxiety refers to feelings of anxiety, dread, nervousness, and associated bodily symptoms related to doing mathematics. As seen in the definitions, there could be relationships between mathematics students' attitude toward success, mathematics anxiety, and self-confidence in learning mathematics. Thus, in the present study these variables are taken as predictor variables to explain self-confidence in learning mathematics.

### **Data Sources**

In this study 841 ninth- grade students (374 females and 467 males) participated in the 1999-2000 academic year. The study was conducted with a conveniently selected sample of students from both private and public high schools in Ankara- Turkey.

### **Instruments**

In the present study, data were collected through using the Mathematics Achievement Test (MAch) developed by Bulut and Tag (2000). It consists of 20 multiple-choice type questions. Item discrimination powers and item difficulty powers were computed. The validity of the test was confirmed by a mathematics educator and a mathematics teacher. Its alpha reliability coefficient was found as 0.81.

We also used the scales that Bulut and Tag (2000) adopted from Fennema and Sherman scales: Self-Confidence in Learning Mathematics (Con) Scale, Attitude Toward Success in Mathematics (AtSc) Scale, Mathematics Anxiety (Anx) Scale, Father (FcSt) Scale, Mother (McSt) Scale, and Teacher (TcSt) Scale. One of the item, "My mother/father hates mathematics" was removed from the Father and Mother Scales because they are not related to mothers'/fathers' opinion about their children. The other scales consist of 12 Likert-type items. The items in the scales had 5 response alternatives: strongly agree, agree, undecided, disagree and strongly disagree. While positive items were scored from 5 to 1, negative items were scored from 1 to 5. The alpha reliability coefficients for each scale range from 0.79 to 0.93.

## Results

### Correlational Analyses

We present in Table 1 pearson correlations, means, and standard deviations for study variables [Criterion variables: self-confidence in learning mathematics (Con); Predictor variables: mathematics achievement (MAch), attitudes toward success in mathematics (AtSc), mathematics anxiety (Anx), gender, perceived father characteristics related to students (FcSt), mother characteristics related to students (McSt) and teacher characteristics related to students (TcSt)]. Low correlations between predictor variables in Table 1 indicate that the multicollinearity was not a problem.

**Table 1.** Correlations, Means, Standard Deviations for Seven Variables

| Variables | Con    | MAch   | AtSc   | Anx    | FcSt   | McSt   | TcSt   |
|-----------|--------|--------|--------|--------|--------|--------|--------|
| Con       | -      |        |        |        |        |        |        |
| MAch      | .34*   | -      |        |        |        |        |        |
| AtSc      | .39*   | .22*   | -      |        |        |        |        |
| Anx       | .71*   | .22*   | .28*   | -      |        |        |        |
| FcSt      | .42*   | .25*   | .44*   | .30*   | -      |        |        |
| McSt      | .40*   | .22*   | .41*   | .24*   | .59*   | -      |        |
| TcSt      | .47*   | .18*   | .35*   | .46*   | -.40*  | .38*   | -      |
| Gender    | .06    | .01    | -.06   | .07*   | .02    | -.02   | -.06   |
| Mean      | 42.328 | 10.845 | 52.408 | 41.451 | 46.214 | 41.342 | 42.328 |

### Regression Analysis

Multiple Regression Coefficient (MRC) Analysis is conducted in order to test the relationship between mathematics achievement, attitudes toward success in mathematics, mathematics anxiety, gender, perceived father, mother and teacher characteristics related to students, and the self-confidence in learning mathematics. The data analysis indicates that gender is not a significant predictor variable for criterion variable ( $p > 0.05$ ). So, this variable was removed and MRC is accomplished one more time. The variables related to the results of this analysis are given below:

As seen in Table 2 there is a significant relationship between self-confidence in learning mathematics and linear combination of the predictor variables: MAch, AtSc, Anx, FcSt, McSt and TcSt ( $F = 212.963$ ,  $p < 0.05$ ). Approximately 61% of the variation in the self-confidence in learning mathematics are explained by the variation of the combination of predictor variables ( $R^2 = 0.61$ ).

**Table 2.** Summary of MRC Results for Combined Effect of Six Predictor Variables

| Regression Statistics          |     |           | Values   |         |        |

\*p &lt; 0.05

As indicated in Table 3, mathematics achievement, attitude toward success in mathematics, mathematics anxiety, students' perception of their parents' and teachers' characteristics related to students are significant factors affecting self-confidence in learning mathematics. The empirical model constructed by the significant factors is:  $Y = -2.357 + 0.248X_1 + 0.134X_2 + 0.481X_3 + 0.009X_4 + 0.169X_5 + 0.009X_6$ ; where Y is "self-confidence in learning mathematics" and  $X_i$ 's are variables identified in Table 3.

### Conclusions and Implications

We can predict the student's self-confidence in learning mathematics by using above equation included MAch, AtSc, Anx, FcSt, McSt and TcSt. In other words, students' self-confidence in learning mathematics is affected by their mathematics achievement, attitude toward success in mathematics, mathematic anxiety and per-

ceived attitude of father, mother, and teacher toward one as a learner of mathematics. The results of the present study are consistent with the study of Armstrong (1981) who found a strong relationship between mathematics achievement and self-confidence in learning mathematics. Like Wang, et al. (1996), we revealed that students' family background influences their self-confidence in learning mathematics. On the other hand, the findings of the present study, unlike Hyde, et al. (1990), could not show that gender is a significant factor determining self-confidence.

The effect of the combination of these variables on self-confidence in learning mathematics is very important because the variation of this combination on self-confidence in learning mathematics is 61 percent. There is a statistically significant relationship between criterion variable and predictor variables. Consequently, we should improve student's self-confidence in learning mathematics and organize our mathematics instruction by taking into account all study variables stated in the present study.

## **EXPLORING THE TEACHER'S ROLE IN DEVELOPING AUTONOMY**

Andy Carter  
Roosevelt University  
acarter@roosevelt.edu

M. Jayne Fleener  
University of Oklahoma  
fleener@ou.edu

Understanding students' mathematical thinking and efforts to improve instruction have focused on classroom discourse "designed to illuminate what is entailed in a 'discussion' and to probe the specific moves that teachers and students engage in that lead to productive rather than unproductive discussions" (National Research Council, 2001, p. 359). This paper investigates the interactions of a group of fourth grade students and their teacher by providing a detailed description and analysis of a classroom episode of group problem solving. In particular we explore how interactions within the classroom's micro-culture impact the development of individual and group autonomy. The purpose of this paper is to deepen our understanding of the ways in which teachers and the social contexts of their classrooms can promote or restrict the development of autonomy through discourse.

### **Theoretical Considerations**

In Piaget's (1973/1948) view, the central purpose of education is the development of autonomy. This view is consistent with current reform movements in education particularly in mathematics (Kamii & Dominick, 1998; Yackel & Cobb, 1996). Autonomy also plays a key role in complex adaptive systems theories, where autonomy is defined as the capacity for self-regulation. In both of these cases, autonomy does not imply "freedom" as the term is generally used; rather it is an individual's capacity to act in accordance with core knowledge and values (Deci, 1995; Kamii, 1994), responding to environmental factors in intelligent and adaptive ways. According to Piaget, unequal power or authority relations tend to constrain the development of autonomy while cooperation encourages reciprocal interaction and the growth of individual autonomy. For Piaget cooperation meant, "striving to attain a common goal while coordinating one's own feelings and perspectives with a consciousness of another's feelings and perspectives" (DeVries, 1997, p. 5). It is characterized by mutual respect in which adults seek to minimize their use of authority while providing opportunities for children to practice governing their own behavior.

The development of individual autonomy is determined by interactions and the social contexts in which they occur. By engaging in the process of self-determination through autonomous action individuals learn how to make better decisions and thereby develop their own creative potential. Thus the growth of individual autonomy is supported in a social context of mutual respect, cooperation, and freedom of choice. Likewise it is constrained in a context of coercion, competition and control. Since it is apparent that social context plays a key role in the development of individual auton-

omy the idea of socio-autonomy (Fleener & Rodgers, 1999) is introduced to provide a theoretical lens for examining the social dynamics associated with its development.

Although socio-autonomy shares many of the characteristics associated with cooperative learning, it is defined as an aspect of the dynamics within a social context rather than a set of actions or organizational structure. Socio-autonomy describes how groups develop their own identities and autonomous characteristics that may support the development of individual autonomy. Some key features of socio-autonomy are: shared meanings; communication; active engagement in common purposes; opportunities for meaningful choice making; and “dialogical encounters” in which “one begins with the assumption that the other has something to say to us and to contribute to our understanding” (Bernstein, 1992, p. 337).

In analyzing classroom interactions we use Wittgenstein’s (1953) view of language games as communication networks within social contexts and Sfard’s (2000) conception of thinking as “communication with one’s self” (p. 297). For the researcher, Sfard (2000) contends, we need to (re)conceptualize what we may mean by communication and how we can define communication as a process rather than as a bartering, exchange, or conduit of ideas. She shifts attention to Wittgenstein’s approach to the construction of meaning. Rather than looking for underlying structures or meanings, Wittgenstein explored the emergence of meaning as language-games. To employ this method in educational research, Sfard suggests exploring not the meanings of discourse, *per se*, but the discourse itself from which meanings, intentions, understandings, and feelings can be examined as a way of reading the language-game.

Wittgenstein’s language-games conception of communication considers the emergence of meaning as evolving through use and social context rather than correspondence. Language games are the enactment of social dynamics and thus are the existing meaning structures in specific social settings. At the same time, language games reveal the dynamics among authority, autonomy and the construction of shared meanings. Language games get played out in a social context, and thus, meaning is understood from a social perspective. Rather than language as the origin of meaning, Wittgenstein remarks, “to imagine a language means to imagine a form of life” (Wittgenstein, 1953, section 19), implying that who we are and how we live are fundamentally related to the language we use. Meaning is understood not as something outside of language, but emergent as language in use. “Meaning is never going to be satisfactorily explained by pointing to the mental, to things like intention” (Genova, 1995, p. 120). The difficulty with denying that words have meaning, however, is not the problem of meaning as reference but shared meanings. How is communication possible at all? How do we use language to derive meaning and share understandings? From a Wittgensteinian perspective communications and thus shared meanings are possible because we engage in language games. This understanding of language games is consistent with social systems as meaning structures and Sfard’s conception of thinking as a form of communication. The language-games being played are integral, inseparable and indis-

tinguishable from the meanings that are being constructed during discourse. We will follow Sfard's approach by observing student and teacher actions and interactions in analyzing communication and the construction of shared meanings. We will look to the language games being played in a brief classroom episode in order to better understand these classroom interactions and the implications they have for teaching.

### **Social Context**

The Benjamin Banneker Elementary School is a school-within-a-school. It is a part of the larger Adams Public School, which is located on the far south side of Chicago. It is also a part of a loosely organized network of more than one hundred "small schools" within the Chicago Public Schools. The entire Adams School had an enrollment of 550 students in the 1996-97 academic year when the data described here were collected. Eighty-nine percent of these students are from low-income families and 98.8% are African-American. The Benjamin Banneker School first opened its doors to students in the fall of 1996. The school's origin can be traced to two years earlier when a group of Adams teachers began to meet and organize a new school based upon a shared vision of educational reform. In the "Benjamin Banneker School Vision Statement" they describe their goal as creating a school where "all children can succeed and feel good about themselves and where learning is a joy due to creative leadership and innovative teaching." One of the early decisions made by these teachers was the adoption of *Math Trailblazers*, a "Standards based" K-5 mathematics curriculum developed with NSF funding at the University of Illinois at Chicago. The lesson presented here is taken from a third grade *Math Trailblazers* unit that focuses on fractions.

The interactions presented here came from a single lesson taken from a series of videos made during regular classroom visits occurring over a one-year period. Although the interactions described here were common for this classroom, this particular episode was not selected as a general representation of the class as a whole. Rather, this episode was chosen for analysis because of the variety of discursive patterns found in an extended interaction involving the students and their teacher. The group consists of four girls, Tiffany, Diane, Mary, and Tina. Tiffany describes the specific problem task at the beginning of the transcribed dialogue.

### **The Fair Shares Lesson**

The class begins with a student reading the instructions out loud for the problems and students cutting out paper pizzas to assist them in their work. After about ten minutes the teacher stops the class and asks another student to read the directions again. She then asks the class to explain what the instructions mean by the phrase "dividing fairly." The first student responds by describing a situation in which she has experienced sharing. Another student explains: "everyone gets a piece." The teacher follows up by asking: "How many pieces?" to which the student responds "an equal number of pieces." Other students respond that to share fairly means that "everyone receives

the same amount”, “the pizzas are divided equally”, and that “they had a congruent amount.” The teacher summarizes the discussion by repeating one student’s response “to share fairly means everyone receives the same amount.” She then instructs the students begin working on the problems in their small groups.

### Small Group Interactions

For about the next 45 minutes all seven of the student groups appear to be actively engaged in solving the problems as the teacher moves around the room providing assistance to various groups. The interactions, which are described here occurred near the beginning of the group work and lasted for about ten minutes. Our observations begin as the group is completing the initial task of cutting out the “pizzas” and starting to work on the assigned problems. The group is working together cooperatively and has assumed an independent identity characteristic of socio-autonomy. Each of the girls appears to be busily engaged in a task related to the problem and over-all group focus. Tiffany is quietly reading the problem to the group while Mary carefully counts out 10 paper pizzas to each of the girls and Diane is cutting out the last of the pizzas. Tina, who has been providing some leadership for the group, appears to be thinking as she writes something down on her paper. A few moments earlier she has initiated a creative problem solving approach by enthusiastically asking Tiffany to play the role of Amber from the problem. Now, after further thought, she says to Tiffany:

*Tina:* Tiffany what’s the question?

*Tiffany:* OK. (Tiffany reads the question from the textbook louder this time as Tina listens attentively and the other two girls continue their work.) Amber, Mario, Denise and Jake have a pizza they want to share fairly. How much pizza will each one get?

Tina is writing on a piece of paper while Tiffany reads the question. Just as Tiffany finishes reading the teacher walks up behind Tina and stands quietly listening to the group.

*Diane:* How many pieces?

*Tina:* (Counting the number of names in the problem) 1, 2, 3, 4, so each person would get two pieces of pizza.

*Teacher:* (this unexpected response of “two pieces” catches the teacher’s attention and she enters the discussion) O.K., how many? (She holds a paper pizza up in her hand.) They have one pizza they’re working with right?

*Girls:* Yes—

*Teacher:* O.K. now what does that question say?

*All the girls together:* How much will each one get?

*Teacher:* So how many people are getting a pizza?

*Two of the girls:* 4

*Mary:* (who appears to be in deep thought and also ignoring the teachers question, jumps ahead with her answer and begins speaking at the same time as the other two girls)  $1\frac{1}{2}$ , they're getting  $1\frac{1}{2}$ .

*Teacher:* (directed to Mary who has caught the teacher by surprise with her unexpected answer) So if you have one pizza and each gets a fair share ...

*Mary:*  $1\frac{1}{2}$  (Mary interrupts)

*Teacher:* Baby its 1 pizza not 4.

Here the teacher is clearly trying to help Mary understand the problem, but she also fails to make any attempt to understand Mary's answer of  $1\frac{1}{2}$ . Mary responds with this same answer, " $1\frac{1}{2}$ " at least five times during the episode. It seems that, for Mary, " $\frac{1}{2}$ " is her fraction word and her answer of " $1\frac{1}{2}$ " is equivalent to "Each got one piece--a fractional piece. Even though Mary's answer did not fit into the language being used in her mathematics classroom to describe the fractions, she was clearly trying to engage in the language games of mathematics being played in her group. But since no one attempts to find out what she means by " $1\frac{1}{2}$ ," an opportunity for her to receive valuable feedback and possibly improve her understanding of fractions is missed.

Responding to Mary's apparent confusion, Tina continues her leadership role by attempting to explain her answer to Mary. Tina's attempt to help Mary understand might have been an indication of Tina's interest in having fun with the mathematics, making it relevant, or helping the group come to a shared understanding of her answer. It's not clear, however, whether the others, including the teacher, were open to playing along with Tina's new language game. And before Mary has time to respond to Tina, the teacher tries to clarify Tina's explanation saying, "Oh, you're going to cut it into 8 slices?"

From this point forward, an important shift can be observed in the group's interactions. Almost every verbal exchange in this small group is initiated by the teacher and occurs between the teacher and one or more of the students in the group. The cooperative work and dialogical interactions characteristic of emerging socio-autonomy found at the beginning of our observations have now shifted and the teacher has become the focal point of the group's interactions.

After a few more questions from the teacher, Tiffany confidently provides the desired answer of  $\frac{1}{4}$  and the teacher repeats the answer while giving Tiffany an approving nod. Tiffany smiles triumphantly while Diane and Mary appear to be waiting for the teacher's next question. Although the teacher and Tiffany have "solved" the problem by playing in the teacher's language game, Tina has continued working independently on her eight-slice scenario and soon provides this response to a question posed earlier by the teacher:

*Tina:*  $2/8$

*Teacher:* O.K., O.K. now what can we say, you said  $2/8$  and you have  $2/8$  and she said  $1/4$ . (pause) O.K. you said  $1/4$  and you said  $2/8$  now that's two different things, so what does that mean, so what can we say, you're only going to get  $1/4$  and you're only going to get  $2/8$ ? So what does that mean?

*Diane:* Uhh, (excited, stands up, searching for the correct word) Uhhh, well it's a mixed uhm.. and uhmm...uh

*Teacher:* You said each person is going to get  $1/4$  and you said each person is going to get  $2/8$ . What can we say about  $1/4$  and  $2/8$ ? (There is some excitement as the girls search for the correct word.)

*Diane:* They are ...

*Mary:* They are...

*Tiffany:* There are 4 people; hang-on it's like this...

*Teacher:* O.K. one at a time

Here the teacher is attempting to take advantage of Tina's scenario to illustrate the idea of equivalent fractions. The game she is playing is to get her students to recognize that  $2/8$  is equivalent to  $1/4$ . The effort of the group to make sense of her questions about the relationship between sharing a pizza cut into fourths and sharing one that is cut in eighths is confused by an inability of some of the students to understand the language of "amount" versus "pieces."

*Teacher:* Let's listen to Tina.

*Tina:* On my birthday I was having a party and I invited 7 people plus me and...

*Teacher:* O.K. you know what dear, now is it 7 people you're inviting or don't forget we're still on this one here (pointing to the problem in the book), we're still on number 6, think of inviting those 4 people.

*Tina:* So instead of inviting 7 people I invite 4 people and I had a pizza, I had a pizza that was cut into 8 and I wanted to see how many slices everyone would get including me if my pizza was cut into 8.

*Teacher:* So if it is divided into 8 slices, so how many slices would each person get?

*Mary:* (lost in thought, then suddenly speaking up)  $4 \frac{1}{2}$

Mary's response appears to be consistent with her previous responses of " $1 \frac{1}{2}$ ". In her language, she is indicating that each person would get a fractional piece. There are

four people, so there will be four fair shares of a fractional amount. Once again though, no one pursues Mary's answer or tries to make sense of it. Instead Tina continues trying to develop a scenario acceptable to her teacher.

*Tina:* But, but I said 4 people plus me.

*Teacher:* No you have to be counted as one of those people. But remember; let's not get away from the problem.

*Tina:* O.K. O.K. so I would be one of them. So everyone at my party would get 2 slices. *Teacher:* O.K. how can we say 2 slices as a fraction?

*Tina:*  $2/8$

*Teacher:* So now my question--what can we say about  $2/8$  and  $1/4$ ?

*Tina:* (Finally acquiescing to the game the teacher is playing) They are the same.

*Teacher:* O.K. do you know another word for the same?

The teacher has not received the answer she wants, which is " $2/8$  is *equivalent* to  $1/4$ ." She is trying to help her students adopt a more standard use of mathematical language in answering a specific question about the relationship between  $1/4$  and  $2/8$ . When, after further questioning it becomes apparent that the group is not following her reasoning she tries shifting to a more accessible representation of the idea of equivalent fractions.

*Teacher:* Four-eighths equals? —

*Diane:* One-half of the pizza.

*Teacher:*  $4/8$  is *equivalent* to one-half. O.K. so you've answered number 6. What does number 6 say again?

*Mary:* (tries to begin reading the problem but struggles and Tina takes over)

*Tina:* Amber....how many slices of pizza will each person get?

*Mary:*  $1 \frac{1}{2}$

Mary's return to her original answer of  $1 \frac{1}{2}$  is significant but not surprising. It provides compelling evidence that Mary's interactions during these exchanges have done little to alter her understanding of fractions or to change her mind about the correct answer. Her use of "fraction language" is different from that of her teacher. Without trying to make sense of the fractional language being used by the other, neither has improved their understanding of what the other is trying to say. Confounding communications about fractions is the conflated use of fractional language to describe, "how many pieces" rather than "how much pizza" each person receives in a particular scenario. These students, it seems, are still relying primarily on counting strategies rather

than working with fractions on a deeper conceptual level as equal parts of a whole. The teacher tries to make the transition from discrete quantities to fractional relationships, but within the current language game, the students are unable to follow the new script. While the teacher is trying to get her students to play in the game by using the standard fractional words, fractional concepts as negotiated meanings are not part of the game.

### Discussion

Our observations began with a group of four girls working together cooperatively. In the first observed interaction between Tina and Tiffany, we see Tina excitedly asking Tiffany to play the role of "Amber." With these actions she appears to be exercising leadership of her group in at least two directions. On the one hand she is focusing her efforts on the assigned problem while at the same time trying to make the process more interesting by asking Tiffany to role-play a person from the problem. Tina continues her leadership by asking Tiffany "What is the question?" Tiffany reads the question and Tina quickly solves it with the creative and unexpected solution of "two pieces." In so doing, she has bypassed the most simple and direct solution to the problem and introduced a new avenue of questioning. All of these actions are carried out in a playful and energetic way as Tina uses her enthusiasm and leadership to pull the others in her group into the language game she has initiated.

Although Tina appears to be giving the group strong leadership, each of the other girls is also engaged in a task related to solving the problem. Not only is the group working together in a self-sustaining way to solve the assigned problem, they are also generating new and potentially more interesting problems as a result of their interactions. Since these students have chosen to work together cooperatively towards a common goal, the group appears to have taken on a life of its own and we see the emergence of socio-autonomy. It is in social settings such as this, where students have the opportunity and motivation to make and learn from their decisions that the development of autonomy is most likely to occur. Creating a social environment where cooperative work like this can occur is a complex and challenging task for any teacher. To have brought her class to this point is a significant accomplishment, which requires both thoughtful preparation by the teacher and a curriculum like *Math Trailblazers* that emphasizes cooperative problem solving.

Shortly after Tina gives her unexpected answer of "two pieces," before we have an opportunity to see how the group will respond to Tina, the teacher enters the discussion. Her intentions are to facilitate the group's discussion by steering it in an appropriate and pre-determined direction. But the group dynamics from this point forward are significantly altered and become dominated by the teacher's understanding of her role as a teacher of mathematics. This understanding of her role is clearly illustrated in her interactions with Mary. Even though Mary sticks with her answer of  $1\frac{1}{2}$  throughout the discussion the teacher never stops to probe what Mary may have meant by this answer. Meaning in the sense of a medium of communication does not occur once the

language game focuses on students' adopting particular understandings rather than engaging in discourse that allows meanings to emerge through the discursive process. The teacher tries to correct Mary's mistake, a realistic understanding of her role as the teacher, rather than hermeneutically listening (Davis, 1997) to Mary's response. Although she uses a variety of well-intentioned approaches in trying to help Mary get the "correct" answer, Mary's answer remains unchanged. Their actions, as seen from a language games perspective, indicate communication, as a medium for meaning evolving through language games, has not occurred. There is no evidence of the types of negotiation necessary for the construction of shared meanings as communications.

It may seem disappointing that a competent, well prepared teacher using a curriculum designed to emphasize student participation in problem solving, appears to see her role as (1) getting her students to adopt the standard language of mathematics and (2) directing her efforts toward telling students what they need to know rather than listening to determine what they understand. An alternative interpretation of these findings is to recognize the complex challenges that occur when teachers who are accustomed to traditional pedagogical practices seek to bring about educational transformation. Teachers engaged in such attempts are inevitably faced with the conflicting demands of teaching for understanding versus covering content; supporting the development of autonomy versus maintaining classroom control; and the social negotiation of meaning versus the efficient transfer of specific information. All of these conflicts and the constant lack of resources and support add to the daunting challenges faced by teachers such as the one described here who seek to bring about educational reform.

### Changing our Vision of Teaching

In his development of the idea of "vision" Wittgenstein distinguishes between having a world-view and having a world-picture. For him, a world-view implies a vision of the world as a static unchanging reality waiting to be discovered, capable of transmission from one individual to another (Wittgenstein, 1969). Unfortunately, schooling, with a focus on the teaching-learning relationship, at least according to Wittgenstein, takes on an air of indoctrination by measuring learning against the yardstick of a *Weltanschauung*.

Traditional mathematics instruction engages the teaching-learning dialectic to advance a particular *Weltanschauung* implicating instruction as well defined concepts and procedures that are to be passed from teacher to student. In this model of teaching the social negotiation of meaning and dialogical interactions are of little value since knowledge is pre-determined and always passed from teacher to student. Also the development of autonomy is thwarted since discourse fails to facilitate communications as the medium of meanings and rather promotes a particular world-view.

While *Weltanschauung* is static, *Weltbild* is dynamic and evolving as we add to and alter it with each new experience. Wittgenstein associates *Weltbild* with "seeing-as"; a way of seeing that is more about making connections than identification and

naming (Genova, 1995). An aspect of experience and revealed through language games, *Weltbild* evolves as seeing-as changes.

I contemplate a face, and then suddenly notice its likeness to another. I *see* that is has not changed; and yet I see it differently. I call this experience “noticing an aspect.”...The expression of a change of aspect is the expression of a new perception and at the same time of the perception’s being unchanged....‘See-as’...is not part of perception...it is related to the experience (and)...it can also be called the expression of thought...you are also *thinking* of what you see. (Wittgenstein, 1953, pp. 193-197)

From an instructional perspective, adopting Wittgenstein’s ideas of a *Weltbild* and “seeing-as” offers important advantages. First if teachers adopt this view then mathematics is seen as an ever changing, evolving construction shaped both by social interactions and individual thought. The focal point of instruction then becomes the conceptual development of mathematical ideas through dialogical interactions, social negotiations and the construction of shared meanings. Secondly, understanding the importance of language games as on-going mediums for meaning, the teacher’s role shifts from getting students to use pre-determined language and concepts to listening and engaging students in knowledge-in-context (Applebee, 1996). The discourse domain of mathematics then becomes a *Weltbild* and not the *Weltanschauung* found in traditional mathematics instruction. Within the social context of the classroom, mathematics curriculum as conversation, engaging in the discourse domain of mathematics, and seeing the world as mathematical contribute to both emergence of socio-autonomy and the development of individual autonomy.

The significance of this study for changing our ideas about curriculum include developing a model of interpretation for classroom language dynamics and deepening our understanding of the social contexts which support the development of autonomy. The perspective of language games *as* meaning rather than as ways of understanding some underlying meaning structures is crucial to understanding an emergent curriculum founded on the principles of self-organization and social meaning structures. In order to move toward the integration of these curricular ideas into instructional practice we must first find effective ways of altering our vision of mathematics. We must move from the widely held view of mathematics as an unchanging set of concepts and procedures to a dynamic vision of mathematics as an ever-changing socially negotiated construction. While we may still find value in the mastery a specific *Weltanschauung* of mathematics, how powerful and gratifying it would be for teachers and students to see the world as mathematical relationships, and to participate together in the creation of a *Weltbild* of mathematics.

## THE COMPLEXITY SCIENCES AND THE TEACHING OF MATHEMATICS

Brent Davis  
University of Alberta  
brent.davis@ualberta.ca

Elaine Simmt  
University of Alberta  
elaine.simmt@ualberta.ca

We report on a year-long teaching experiment in which principles of complex emergence were used to frame activities and interactions within a junior high school mathematics class. We begin with a brief introduction to complexity science, endeavoring to situate the discourse alongside contemporary theories of learning, knowledge, and culture. This discussion is used to frame the report of the teaching experiment, which is in turn used to illustrate an examination of some pragmatic aspects of complexity science research for mathematics teaching practice.

Complexity science is interested in questions of emergence—that is, in those instances when coherent collectives arise through the ongoing effort of individuals to maintain their fit within evolving circumstances. These sorts of phenomena might be further described as ‘bottom-up’, as emergent macrobehaviors arise through localized rules and behaviors of individual agents, not through the imposition of top-down instructions.

On these counts, complexity science is more a metadiscourse than a new field. It has arisen in the coalescence of relatively isolated research efforts and insights across economics, sociology, psychology, neurology, political science, and other academic domains. (See Capra, 1996 and Johnson, 2001 for extended lists.)

Weaver (1948), in an article that is regarded by many as seminal to complexity science, was among the first to formally categorize those phenomena that have become the subjects of complexity science research. In fact, he distinguished among three sorts of phenomena. The first category, *simple systems*, includes those dynamic events that involve only a few interacting parts or variables. Framed by the insights of Galileo, Descartes, Newton, and their contemporaries, such systems include simple trajectories, billiard ball collisions, orbits, and the like.

As was recognized early on, the analytic tools developed to describe and predict such simple interactions can give rise to intractable calculations when the number of interacting components increases only slightly. In the 19<sup>th</sup> century, as scholars met up with more and more such phenomena, new analytic tools based on probability and statistics were developed. These methods were useful for the examination of phenomena that might involve millions of parts or variables—in Weaver’s terms, *disorganized complex systems*. The development of statistical and probabilistic methods was more a resignation than a shift in thinking. The driving assumption was still deterministic, consistent with Laplace’s (1795/1951) often-cited pronouncement:

Given for one instant an intelligence which could comprehend all forces by which nature is animated and the respective situations of the beings which compose it—an intelligence sufficiently vast to submit these data to analyses—it would embrace in the same formula the movements of the greatest bodies and those of the lightest atom; for it, nothing would be uncertain and the future, as the past, would be present to its eyes. (p. 4)

The move to probability and statistics, then, was an acknowledgement that no flesh-based intelligence was sufficiently vast. The more intricate and complicated the phenomenon, the more one was compelled to rely on descriptions of gross patterns rather than on analyses of interacting factors.

Weaver was among the first to note that these two categories—simple systems and disorganized complex systems—did not cover the full range of possibility. Specifically, they omit those phenomena in which the interacting parts themselves are not inert or mechanical, but fluid and co-specifying. Such phenomena as societal coherence, cultural evolution, and brain function, for instance, do not readily submit to analytic and statistical tools. The essential quality of phenomena in this category is that they maintain some level of coherent organization.

*Organized complex systems*, as Weaver named them, represent a rejection of determinism and a demotion of analytic reduction. A different sensibility is required for their study, in large part because a comprehensive knowledge of the parts that comprise such systems is not adequate for the prediction of the qualities or behaviors of the collectives. The problem here is not a matter of inadequate calculation power; it is a matter of the sorts of transcendent possibilities that emerge when complex unities cluster into more complex unities.

The adjectives ‘disorganized’ and ‘organized’ have since been dropped in discussions of complexity, in favor of a more fundamental distinction between ‘complicated’ and ‘complex’. As Waldrop (1992) develops, complicated is used by complexity scientists to refer to deterministic, mechanical events, and thus includes both simple and disorganized complex systems. Complex, in contemporary parlance, is used to refer to what Weaver described as organized complexity.

Over the past 30 years, the emergence of complexity science has paralleled the embrace of non-representationist epistemologies among mathematics education researchers. The two trends are compatible on several counts, including shared emphases on post-Darwinian evolutionary dynamics and a greater use of biology-based metaphors to describe knowing, knowledge, and other complex phenomena. The movements, however, are not coterminous, as becomes clear through comparisons of their objects of study and the utility of their conclusions. Regarding the objects of study, contemporary non-representationist discourses tend to be focused on particular, well delineated phenomena. Radical constructivism, for instance, follows Piaget in its focus on the individual’s construals of the world (von Glasersfeld, 1995), whereas

particular social constructivist discourses might focus on the emergence of a particular body of knowledge (e.g., Ernest, 1991), cultural sensibilities (e.g., Skovsmose, 1994), or some other collective phenomenon. Complexity science, by contrast, collects together such phenomena as individual sense-making, collective knowledge, and social habitus as a class of phenomena.

At the same time, however, complexity science explicitly rejects any attempt to collapse such phenomena into instances, variations, or elaborations of the same thing. A core tenet of the discourse is that complex unities must be studied at the levels of their emergence, as new possibilities arise and new rules apply in each case. A perhaps surprising implication of this assertion is that discourses that are concerned with different phenomena (such as radical and social constructivisms) can be simultaneously valid and incompatible. For instance, the implicit dynamics of individual sense-making and collective knowledge (or neuronal interaction, stock market behavior, etc.) may be similar and co-implicated, but the events themselves cannot be collapsed into or mapped onto one another.

In its first few decades of development, complexity science consisted mainly of descriptions of various complex systems. More recently, Johnson (2001) notes, the emphasis has shifted toward more deliberate efforts to trigger complex emergence. Much of the current work in complexity science is concerned with the identification and manipulation of the qualities that are common to all complex systems—that is, the conditions that must be present for agents to come together into collectives that might supersede the possibilities of those agents on their own. On this count, complexity science suggests that the *possibility* exists for transcendent collectivity wherever self-specifying agents are allowed to interact. However, as has been demonstrated in many mathematics classrooms, something more is needed for complex emergence than proximity, common goals, and common tasks.

Unfortunately, because complexity is a-deterministic, the “something more” that is needed cannot be specified. A shift in interpretive focus is required here, away from what *must* or *should* happen toward what *might* or *can* happen. Pragmatically speaking, efforts to occasion complexity revolve more around the specification of boundaries and conditions than around efforts to prespecify outcomes and means—or, as Varela (1987) frames it, on proscription rather than prescription. Proscription is a matter of what is not forbidden is allowed, versus the more prescriptive attitude of what is not allowed is forbidden. Proscriptive situations include, for example, most games, social interactions, business dealings, and artistic endeavors. In formal and explicit terms, these sorts of activities are framed more by what one must not do than by what one must do.

At first glance, applied to discussions of school mathematics, this prescription/proscription distinction might seem to map onto the extremes of popular debate. At one end of the spectrum, the caricature of a strictly rote-based, ‘traditional’ classroom

seems the epitome of a prescriptive situation. On the other end, an exploration-oriented, student-centered, 'progressive' classroom appears to embody a proscriptive sensibility. Such a mapping, however, is not entirely appropriate.

The difficulty arises in the extreme interpretation of the progressive classroom, in terms of an anything-goes abandonment of rigid structures and imposed expectations. A proscriptive attitude does not necessarily support such moves. In fact, proscription is not an abandonment of constraints, but a shift in thinking about the sorts of constraints that are necessary for generative possibility. As Johnson (2001) explains, complex emergence occurs in rule-governed systems:

their capacity for learning and growth and experimentation derives from their adherence to low level rules.... Emergent behaviors, like games, are all about living within boundaries defined by the rules, but also using that space to create something greater than the sum of its parts. (p. 181)

### Occasioning Complexity in a Mathematics Classroom

We turn now to an account of a classroom event that was explicitly informed by principles of complex emergence. Specifically, the lesson (taught by Simmt) incorporated the necessary but not sufficient conditions of internal diversity, redundancy, decentralized control, organized randomness, and neighbor interaction. The meanings and significance of these notions will be elaborated in the discussion that follows our report of the event.

The episode unfolded in a Grade 7 classroom, near the end of November, two weeks into the study of integers. The initial focus of the unit was to render explicit the sorts of applications and images that students brought to the topic—including number lines, thermometer scales, profit/loss figures, and altitudes, as well as more primitive (and more tacit) images for counting and other binary operations such as set/container schemas and path schemas (see Lakoff & Núñez, 2000).

In this lesson, students were asked to consider the statement, " $3 \times -4 = ?$ " They were paired off (by the teacher) and each pair was given ten minutes to agree on a product and to "Show how you know"—that is, to prepare an explanation on chart paper for presentation to their classmates.

In our analysis, students' responses fell into five categories:

- *grouping of objects*, whereby  $3 \times -4 = -12$  was described and explained as three groups of four negative chips;
- *number line movement*, where  $3 \times -4 = -12$  was interpreted as three hops of length four, starting from zero, moving in a negative direction (which was not always presented as the conventional leftward or downward);
- *repeated addition*, where  $3 \times -4 = -12$  was rewritten as  $-4 + -4 + -4$ , and the already established rules of addition invoked;

- *appeal to external authority*, of either a previously learned rule or the answer generated with a calculator;
- *extending a rule*, in which one pair determined the magnitude of the product by ignoring the signs (i.e.,  $3 \times 4 = 12$ ), and assigned the product a negative value “because the minus was on the bigger number”.

A feature of these presentations (which took up the rest of the 50-minute block) was that the students closely attended to one another’s responses and explanations, without prompting or nagging from the teacher. Their engagements with one another’s work were notable around two explanations in particular: the case of extending the rule and one version of repeated addition.

Unfortunately, the case of extending the rule came too late in the session, and there was no opportunity to pursue the challenge, raised by the teacher, that while this strategy gave the same response as the other to  $3 \times -4$ , it would not for  $4 \times -3$ . It did, however, fulfill a sort of cliffhanger function as some students began to engage in rather heated debate as the bell rang and as they filed out of the room.

In the other noted case, one of the pairs that had written on their poster that “ $0 + -4 + -4 + -4 = -12$ ”. The zero had clearly been squeezed into the left margin of the page, apparently added after the rest of the statement had been written. Noticing that point of difference from the other groups, Simmt asked about the zero. As a member of the pair pointed to a classmate in a different group, he explained, “He said that we have to start somewhere”. In other words, although the explicit representation offered by this pair was a case of multiplication by repeated addition, that interpretation was rooted in the image of movement along a number line.

The pair’s response about their inclusion of a zero in the sum prompted some rumbling in the room, amid which another student, Tim, announced that “It actually doesn’t matter where you start from. It will be the same”. As neither the original explanation nor Tim’s elaboration had yet been explicitly linked to the number line image, the teacher asked Tim to say more. In response he offered, “Well, negative four, three times, is always negative twelve, even if you start somewhere else”.

### Interpreting Complexity

We focus our analysis on just the two interpretations developed in this already very partial account. We have organized this section as five intertwined discussions of some of the conditions necessary for complex emergence, as mentioned above.

#### Internal Diversity

In complexity terms, intelligence is about the capacity to respond not just appropriately, but innovatively to novel circumstances. The key to intelligent response is the diversity represented among a system’s agents, as a system’s range of possibility is dependent on the variation among and mutability of its parts. Pools of internal diversity enable a system to respond in flexible ways, in response to shifts in circumstance, whether internal (among agents) or external (with the context) to the system.

An orienting principle of the lesson as taught was the importance of diverse contribution. As such, the task,  $3 \times -4$ , was not heard by most as a challenge to home in on a definitive rule or explanation, but as a place to articulate and compare different ideas. Even the pairs that seemed to frame their activities in terms of rule-generation were very much part of this diversity game. A member of the pair that extended the rule was quite proud of the fact that their response differed from all of the others.

The importance of diversity was perhaps most evident in Tim's contribution—in particular, his point that it doesn't matter "if you start somewhere else". In formal terms, we interpret Tim's thinking to be consistent with a vector-based interpretation of multiplication, where direction and magnitude matter but location does not. Tim's insight is an instance of conceptual blending, in which a property of 'portability' was added to the mix of multiplication as set grouping, repeated addition, and number-line hopping. As Lakoff and Núñez develop, these sorts of metaphor mergers have often occurred in moments of significant advances in the history of mathematics.

Tim's contribution was clearly hinged to ideas that had already been represented. This juxtaposition of diverse interpretations, that is, satisfied the condition of internal diversity.

### Redundancy

A system's capacity to maintain coherence is tied to the redundancy expressed among its agents. Just as internal diversity enables flexible response, internal redundancy is essential to the co-specification of agents. Educators interested in complex interactivity must thus attend to the common ground of participants. In the mathematics classroom, such redundancy involves more than shared vocabularies and resources. Commonalities of experience, expectation, and purpose are also important.

The redundancies that underlie a system's robustness can be difficult to discern, as they tend to serve as the ground of activity, not the figure. Arguably, then, this part of our analysis should be the lengthiest, and had we the luxury of a more full-bodied description of the setting, it would be. In the months preceding the reported episode, Simmt had devoted considerable attention to the development of standards around acceptable explanation and engagement, in addition to an explicit pedagogical emphasis on the sorts of experiences, images, tools, and metaphors that infuse interpretations of various concepts.

The intention of these efforts was to establish a necessary redundancy among participants—that is, to ensure that agents' *individual understandings* were sufficiently compatible to enable the emergence of *collective understandings*. The redundancy among participants was not framed in terms of master of facts and procedures, but on shared standards. Such groundwork, although not the central focus of this analysis, is arguably the main work of the mathematics teacher.

825

### Decentralized Control

Mentioned in a discussion of teaching, the idea of decentralized control might be heard as an endorsement of student-centered instruction and a condemnation of teacher-centered classrooms. It actually is intended to point to quite a different sensibility.

To appreciate this point, one must be clear on the nature of the complex unities that are desired in the mathematics classroom—which, for us, are mathematical ideas, insights, concepts, and understandings. This point prompts our attentions away from matters of teacher- versus learner-centeredness and toward disciplinary knowledge. In this case, the issue is not *who* is at the center, but *what* is at the center.

To be more explicit, traditionalists and progressivists alike have tended to regard the mathematics classroom as a collection of individuals. A complex theoretic presses our attentions to the possibilities of interpreting the classroom as a collective, in terms consistent with Varela's (1999) description of a complex unity:

The whole does behave as a unit and as if there were a coordinating agent present at its center.... [A coherent global pattern] emerges from the activity of simple local components, which seems to be centrally located, but is nowhere to be found, and yet is essential as a level of interaction for the behavior of the whole. (p. 53)

This description, we believe, is an apt one of the emergent understandings in the episode described above. The 'knowledge' in this setting clearly did not reside in any person in particular. Nor was the authority exclusively lodged in one character, one argument, or one resource. The control of the knowledge, that is, was truly decentralized, and that decentralization was necessary for some of the ideas to arise.

This is not to say that the teacher did not exercise a particular authority. Simmt was, in fact, very directive on certain aspects. In particular, the collective rules of engagements were explicit in the manner in which she set the task and embodied in the accumulated history of her responses within the collective. And while such aspects of teaching can be analyzed in terms of power and authority, an interpretation based on such monological metaphors would have to ignore the complex, co-specifying activities during the session. It would also have to focus on the activities of the individuals, rather than on the emergent knowledge of the collective.

### Organized Randomness

Complex systems must exist in disequilibrium, maintaining a delicate balance between sufficient organization (to structure the agents' interactivities) and sufficient randomness (to allow for flexible response). Such balances are matters of neither "every agent does the same thing" nor "every agent does something different", but of all agents participating in a joint project.

We prefer to use another apparent oxymoron—*liberating constraints*—in our efforts to make sense of the implications of this condition of complex emergence for the mathematics classroom. Liberating constraints are those proscriptions that are placed on classroom activity that, it is hoped, will open up rich spaces of interpretive possibility.

Consider, for example, the decision to structure an entire 50-minute block around the item, “ $3 \times -4 =$ ”. On the surface, this might seem a rather severe constraint. But, of course, the lesson was not really about determining the product of 3 and -4, but about the sorts of images and metaphors that enframe and inform discussions and applications of integers and binary operations. (At least, this is how Simmt understood her activity. It is not at all clear that any of the students regarded their engagements in such terms.)

Nor was that particular item the only constraint. Students were also expected to “Show how you know”, a demand that effectively opened the door to a diversity of possibility. Unlike some classroom settings in which such randomness might be ignored or not noticed, in this case it was deliberately represented, displayed, and organized.

Importantly, the point here is not that one must seek to prompt randomness in the mathematics classroom. That quality is always and already present by virtue of the complex natures of human thought and sociality. The challenge for the teacher is to find means of tapping into that wealth of possibility. The posters idea was developed in specific response to this concern, and the resulting artifacts helped to establish a balance between sufficient organization to orient students’ actions and sufficient randomness to allow for flexible and varied response. Phrased differently, the structure of the activity served to mediate individual insights and the collective project of mathematizing.

For us, the deliberate attention to the mediation of individual and collective projects represents a rejection of linearized curricula—and, with that, an elaboration of efforts toward ‘task analysis’. While we believe it important for teachers to have well developed understandings of how mathematical concepts fit together, complexity science prompts us to assert that such analytic understandings must be part of broader appreciations of concepts’ experiential requisites, metaphoric roots, and so on.

### **Neighbor Interactions**

On the surface, it might seem almost unnecessary to develop the point that there must be neighbor interactions in order for complex possibilities to emerge. What is not so obvious, however, is what might constitute a ‘neighbor’ in the context of a mathematics community.

In the rarified and abstracting epistemic body of mathematics, the neighbors that must bump against one another are not physical bodies, but ideas, hunches, and que-

ries—a point that Rotman (2000) underscores in his critique of the popular image of the mathematician as a loner:

If one observes [mathematicians], then it would be perverse not to infer that for large stretches of time they are engaged in a process of communicating with themselves and one another; an inference prompted by the constant presence of standardly presented formal written texts (notes, textbooks, blackboard lectures, articles, digests, reviews, and the like) being read, written, and exchanged, and all informal signifying activities that occur when they talk, gesticulate, expound, make guesses, disagree, draw pictures, and so on. (pp. 7–8)

Taken to the context of the mathematics classroom, an upshot here is that group work, pod seating, and class projects may be no more effective at occasioning complex interactivity than straight rows and textbook exercises—if there is no emphasis on the display, juxtaposition, and interpretation of diverse, emergent ideas. Concepts and understandings must be made to stumble across one another. Without these neighbor interactions, the mathematics classroom cannot become a mathematics community.

Such was the sort of thinking that lay behind the paired interactions, the poster presentations, and the surrounding discussions in the episode reported. These conditions enabled the emergence of an idea not previously considered by anyone in the room, at least not in the terms presented: Tim's merging of the *location-specific* suggestion that "we have to start somewhere" (if multiplication is understood as number-line hopping) with the *location-independent* idea of multiplication as repeated addition. The consequent blending gave rise to the vector-like notion that multiplication is a directed movement of specified magnitude.

### Complexity Science and Mathematics Teaching

For us, the main attraction of complexity science is that it provides means of embracing radical, social, and critical constructivist insights into knowing and knowledge while doing something that these discourses are often unable or reluctant to do: speak to the particular, multileveled, deliberate, and practical concerns of formal education.

To that end, the five conditions discussed in this report are not merely useful tools for after-the-fact analyses of classroom events. They can also be put to instrumental use in the preparation of classroom tasks. For instance, the notion of *internal diversity* points to the need to develop activities that can be adapted by learners to their particular understandings and expectations. *Redundancy* highlights the importance of shared experiences and established standards of engagement. *Decentralized control* points to a need for *all* class participants to be attentive to emergent interpretations. *Organized randomness* foregrounds the importance of setting boundaries and rules—constraints that operate proscriptively rather than prescriptively. *Neighbor interactions* prompts attentions to the manners in which ideas might be represented and juxtaposed.

Again, that such conditions are met in a mathematics classroom is no assurance that complex possibilities will arise. However, a neglect of such conditions will provide a reasonable assurance the collective activity will never exceed any individual's insights.

# TECHNOLOGY AND MIDDLE SCHOOL STUDENT RESPONSE TO MODEL-ELICITING ACTIVITIES: A CASE STUDY

Margret A. Hjalmarson  
Purdue University  
mhjalma@purdue.edu

**Abstract:** Ends-in-view problems often require students to design a generalizable tool for decision-making. To aid the development of such tools, in particular a consumer guide, spreadsheet software can be used to help students develop, test, revise, and refine their products. In the case described here, a seventh grade student uses spreadsheet software to design a consumer guide. The mathematical model used encompasses statistical concepts such as scaling and weighting of variables.

Mathematics education research has explored multiple methods of technology use in the classroom for many years (Kaput & Thompson, 1994). In particular, technology is often used as a computational or instructional aid for students (e.g., Shaffer, 1997; Wilensky, 1995). However, beyond the classroom, the use of technology is also associated with the design of sharable, reusable tools. For the purposes of this paper, a sharable mathematical tool is one designed with a particular purpose or end-in-view even though the exact nature of the tool is not known (English & Lesh, in press). There are particular criteria for designing a useful tool. In particular, it should be clear when, where, how, and why to use the tool in particular situations. For example, a consumer guide should help the consumer make a decision about what product to buy. The consumer guide should reorganize and aggregate data gathered from different products in order to give the consumer a recommendation about what to buy. A consumer guide should be clear about what data were collected and how the information was analyzed. The information should also be presented in such a way that the consumer easily understands the results. Such tools may be used to aid consumers with decision-making, report information, or aggregate information. Spreadsheet software can be used to aid the collection and analysis of data for developing the tool.

Model-eliciting activities are one example of a type of problem that can incorporate tool design and characteristics of ends-in-view problems. In the example given in this paper, a student works on a model-eliciting activity called the *Snack Chip Problem* to design a consumer guide for purchasing snack chips. The student uses Microsoft® Excel to design the consumer guide which allows individual consumers to rate different types of snack chips. First, I elaborate on salient characteristics of model-eliciting activities. Then, I describe the experience of a student working on the *Snack Chip Problem* and characteristics of the development of the consumer guide tool.

## **Ends-in-View Problems and Model-Eliciting Activities**

Ends-in-view problems are tasks requiring students to develop complex products with specific criteria (English & Lesh, in press). The tasks are called “end-in-view” because the students know what the purpose of the product, but they do not know the exact nature of the product. The students are given requirements for the final product

and must sort through available information to design the product. This type of task goes beyond standard word problems where the information given is clearly defined and the students are asked to find some lost tool or operation for transforming the givens to goals. In an ends-in-view problem, the task of the student is often to design the procedure for processing information and to determine what the givens and goals are. There are specific criteria for a successful product, but the exact design of the product is not specified. Often they are producing a sharable, reusable model. So, instead of an answer to a problem, the students are producing a generalizable procedure that can be used for decision-making in multiple problems. For example, the *Snack Chip Problem* is one example of an ends-in-view problem completed by a student described later. It states to students "In this investigation, you will be developing a consumer guide to help people determine which type of snack chip is the best to buy. It is your decision what to focus on in your consumer guide. Your consumer guide must help people in choosing any snack chip, not just the ones you use in this activity." (English, 2001) The students then complete a series of questions asking them to think about different types of variables connected to snack chips. The students often list aspects such as price, nutrition, value, taste, fat content, and calories among other variables. In particular, for the *Snack Chip Problem*, the students develop a tool consumers can use to decide what kinds of snack chips to buy. The students define the important variables and any representations used in the guide to help consumers. The students also collect and sort available data from actual snack chips. The students then use a spreadsheet package (in this case Microsoft® Excel) to develop a tool used to represent the data and help the consumer decide which type of snack chip to buy. When middle school students are given access to a computer with typical word processing and spreadsheet packages, they are capable of producing more complex products than with access only to basic calculators. The tool can be designed within the software packages available on the computer.

In the case of the *Snack Chip Problem*, the end-in-view is the consumer guide for purchasing snack chips, but the students need to interpret the givens and goals of the problem. The relevant variables (or givens) are not specified, and the students need to determine which variables are important and how to formulate the consumer guide (the goal). There are many different kinds of snack chips, and each package has a lot of information on it that could be incorporated into a consumer guide. This situation is similar to real-world problems ranking products from chips to dishwashers to universities. Different rankings incorporate different variables with different weights. The students need to collect data, sort data, and interpret data to meet the end-in-view and define the givens and goals. While processing the data, the students need to keep the end-in-view in mind. Namely, that they need to produce a consumer guide that helps consumers decide which snack chips to buy. However, the exact nature of the consumer guide is not defined.

One important difference between designing a tool and solving a problem is that tool design can incorporate cyclic development. In the case of the consumer guide for

snack chips, a first iteration of the tool can be developed, tested, revised, refined, and tested again. Each of these phases represents a cycle of development. After each cycle, the tool becomes more refined and more sharable and reusable. The testing cycles also helps the student clarify underlying assumptions that go into the making of the tool. The end-in-view helps students determine whether the tool needs to be revised and how to revise the tool. Another important distinction is that students should be regularly asking themselves and others whether the tool works rather than when the answer is right.

One subset of ends-in-view problems are model-eliciting activities that require students to produce a complex tool, description, explanation or model describing a method for solving a problem for a particular client. Their final product is often contained in a letter describing their method for solving the client's problem. They need to describe the method with enough clarity that the client can read the letter and implement the method in a similar problem situation. The method should work not only for the particular task at hand, but also be generalizable to other situations the client may encounter.

An important characteristic of model-eliciting activities that is relevant to using technology and ends-in-view problems is self-assessment. (Lesh, Hoover, Hole, Kelly, & Post, 2000) Self-assessment in this case means that students should be able to examine their developing products and determine whether they are satisfying the criteria for a successful product. Students should also be able to determine what revisions are necessary. Spreadsheet software can simplify the testing of products, but students also need to be careful that they are entering data and formulas correctly by monitoring the results carefully. Spreadsheets also remove some of the computational work involved in data processing, but add the ability to incorporate more variables, add types of data and revise procedures quickly. For example, when solving the *Snack Chip Problem*, a student can enter data, and an equation for computing a score for each type of chip. If the student thinks that one variable needs to have more or less weight than the others, coefficients in the equation can be changed, and new scores can be computed quickly. This revision capability allows for a more refined product. If the student had computed scores by hand, he/she may not want to change the coefficients in the equation and recalculate all the scores. With a spreadsheet, the student can test and then revise procedures more easily to improve the design of the tool.

A second important characteristic of model-eliciting activities is that the problem should be contained in a context in which the students can make realistic assumptions. (Lesh et al., 2000) One part of the reality characteristic is that the problem should be real to the students. In this case, the students understand the need to make purchasing decisions. They also understand which variables might be important to examine (e.g. nutrition, taste, price) since they have either purchased or been with someone purchasing snack chips. So, the context of the problem is immediately accessible to the students. Another part of having realistic constraints and assumptions is to understand what tools would be available to someone in the "real world" solving the problem. In

the case of the *Snack Chip Problem*, spreadsheet software would probably be available to collect and analyze data. Hence, for students solving the problem, a laptop with Microsoft® Excel gives the students the same tools that would be available to a marketing analyst disseminating information about snack chips. The computer software also allows for greater generalizability since it is easier to modify the tool than with paper and/or a calculator. The spreadsheet also allows for more complex representation of information in charts and graphs that can be used as part of the consumer guide.

The *Snack Chip Problem* is also somewhat unique in the types of variables that students can choose to aggregate. First, part of the task for the students is to determine which variables are important. Second, some of the variables are qualitative characteristics that may be quantified (e.g., taste preference) and some are quantitative (e.g., price, fat content). The students may divide the variables categorically (e.g., high and low price). For some variables, high values are good and for others low variables are desirable. The students may also have to scale the values up or down. Variables may also be grouped by type. For example, fat content, sodium content, and sugar content could be aggregated under a nutrition score. Students also need to consider variables with positive or negative relationship with consumer desires. For example, fat content may be subtracted because it is an undesirable characteristic of snack chips. For an ends-in-view problem, students must consider not only the numerical values of a variable, but the type and quality of the variable. Mathematically, these requirements fit within current National Council of Teachers of Mathematics (NCTM) standards for mathematics (NCTM, 2000).

Related to the variables used in the tool (in this case a consumer guide) is that there is a significant amount of data processing and statistical analysis that must occur to develop an effective tool. The students have to determine which variables are important to collect, how to collect the information, how to sort the information, how to organize the data in a spreadsheet, and then how to process the data to give results to the consumer. These phases are not necessarily completed sequentially. As discussed previously, there are often cycles of development in which the tool is revised, refined, and tested repeatedly. Keeping an end-in-view in mind helps the students decide on revisions and determine whether the tool they are developing is both mathematically and realistically useful and effective. The spreadsheet software simplifies revision and testing because the computational requirements are reduced. However, the students must be cautious in accepting results from the spreadsheet and recognize their role in entering data and designing the spreadsheet.

### **Student Solution Case Study**

My goal for the case study described was to investigate the types of products the students produced given access to laptop computers. In addition, I was also interested exploring in the characteristics of the cycles students went through when developing their products, particularly when using technology. There are many studies and examples of paper-based activities (Doerr & Lesh, in press), but less work related to

the incorporation of technology. The student described in this section provides one example of work on ends-in-view problems. The case study represents the beginning of work that can be done in this area, and more extensive research will be necessary to provide more detailed accounts of work in this area and illuminate characteristics of these activities.

The *Snack Chip Problem* was implemented along with a series of eight other model-eliciting tasks during a nine-week Saturday course for gifted fifth through eighth graders. The six students voluntarily enrolled in the course. They completed approximately one model-eliciting task per week during each two-hour class session. They often worked in pairs, but occasionally worked individually. Typically, they worked on the problem for about an hour to an hour and a half, and then made presentations of their solutions to the rest of the class. They began using the laptop computers during the first week of class. Although the classroom situation is fairly atypical, the site served as a forum for testing new types of activities and exploring the possibilities for technology use.

During the first class session, the students completed a survey asking about their motivations for taking the math class, their computer experiences, and their preference for mathematics. The survey served primarily as a tool to help me consider appropriate pairings of the students and understand their interests in taking the course. In a previous semester, I had not given a survey at the beginning of the course and had to rely on individual conversations with the students to determine their interests in mathematics and their computer experience. Knowing their prior experience with computers became especially important because students' comfort and experiences with computers can effect their development of products. Because the activities are designed to be accessible to a variety of students within the class, varied mathematical abilities did not concern me as much in terms of whether the students would be able to develop a product. The nature of the products may vary, but all the students could develop a product with the tools available.

My role in the classroom was as their teacher, but I was also collecting data for this study. To reach the goal of examining the types of products developed by the students, I collected videotapes or audiotapes of students working. I also made extensive field notes immediately after the class sessions ended. In the field notes, I described my observations about their work in pairs. I also noted as much about their cycles of development as possible. Due to my role as teacher in the classroom, it was difficult to make extensive notes during the class while working with the students and taking care of the technology. I also collected their final products to supplement my notes.

I attempted to minimize my intrusion into their work on the activities. I tried not to influence their products with my own opinions as much as possible. The only area where I played a significant role was in helping them work with the laptop computers. I provided any technology help they requested (e.g., formatting documents, finding mathematical functions in Microsoft® Excel, saving documents). For the first week, I chose a less mathematically challenging activity in order to help them adjust to the

new requirements for these activities, the class organization, and to the laptop computers. As the weeks progressed, I tried to choose a variety of activities in terms of mathematical content (e.g. statistics, spatial reasoning, algebra) and contexts.

The *Snack Chip Problem* was solved during the last class session. Developing the consumer guides took the students approximately an hour to complete. To help them complete the problem, I provided eight different kinds of snack chips and their prices. The students could collect any data they needed from the packages and taste the chips if they wanted. At the end of class, they presented their guides to the rest of the class. Each pair had access to a laptop computer with Microsoft® Word and Excel. Typically, they used Microsoft® Word to type their final letters to the client. The students also used Microsoft® Excel for some problems if there was statistical analysis or other data processing.

The student in the transcript excerpts below, Alex, is a seventh-grade boy. He was originally assigned a partner for this session, but they started to work individually a few minutes after starting the activity because they had very different ideas about how to design the consumer guide. Alex asked me if he could work independently. During earlier weeks, I had allowed him and other students to work independently if they wanted to. Alex worked well with other students in general and was an active and enthusiastic participant in the class. For example, after a big snowstorm, he was concerned the class would be cancelled on Saturday. Alex had some computer experience and could use Microsoft® Excel and Word with very little assistance from me. In the survey from the first class, Alex said his favorite subject at school was math “because its not boring; not just memorizing things.”

Alex used Excel to develop the consumer guide shown in Figure 1 and then typed a letter explaining the guide in Word. For example, Figure 1 shows a spreadsheet he developed to solve the *Snack Chip Problem*. The student designed the tool so that consumers could enter information about two kinds of chips and compare scores. The equation to find the total score found in the far right column was  $\text{score} = \text{price} - \text{fat} + (10 * \text{preference}) - (\text{calories}/10)$ . I provided the prices from the store where I purchased the chips for the students. Alex used the number of grams of fat per serving for the fat value. Alex tasted each chip and assigned a preference value between one and 10 with 10 being the best score. Alex used the calories per serving for the calorie value. The calorie values are divided by 10 because the values are usually above 100, and all the other variables had values less than 10. Fat and calories were subtracted because they negatively impacted the desirability of the chips (according to Alex and other students in the class). In developing the score equation, Alex assigned relative weights to variables, scaled variables, and developed a generalizable model that could be extended to different types of chips and other products.

Because Alex was working alone, I asked him more questions than usual as he worked on his guide. During the session, he talked to me, to other students, and to himself. At the beginning of his work, I made a few suggestions that were largely ignored because Alex had a clear idea about the product he wanted to produce. At the

Figure 1. Alex's consumer guide for snack chips.

beginning, his guide appeared to allow only for entry of data about one type of chip at a time as only the first two rows in Figure 1 were on the spreadsheet. Without any prompting from me, Alex said, "I should put two in so you can compare two of 'em at the same time." An effective guide should show more than one type of chip, and he wanted to be able to see scores for two types of chips at once. I suggested he make a score column and reformat the spreadsheet so a consumer could enter more types of chip. He said, "But they're not like doing 'em all at one time usually because it's a guide since it said guide I think." Later, when he collected data from all the eight types of chips I had brought to class, he added the eight rows on the bottom listing the rank ordering of the chips and the scores.

The second type of interaction I had with Alex was as a tester of his consumer guide. Other students worked with partners they could use to test ideas. After developing his first draft of the consumer guide he said to me, "Ok give me two kinds of chips. Ok want to try it now? Want to try it to see if works?" I sat at the computer, tasted the Crunchies chips, and entered data into his spreadsheet. After we got the score (10.78), I asked him what the score indicated. We had the discussion shown in Figure 2.

Asking a second person test the guide with a new type of snack chip helped Alex find flaws in the first version of his guide. After the discussion, he noticed the coefficient he was using for the taste preferences was too low (7) and he needed to raise it to 10. Testing the tool caused a revision of the tool and a refinement of his algorithm for scoring the snack chips. At this point, his intent for the scores once they had been produced was not clear. However, my question and testing did aid a revision to the tool. After he changed the coefficients in the equation, I tested the tool again. This excerpt

A: 10.78  
M: So what does that mean?  
A: I need to change my times 7 back to a times 10.  
M: Ok. So when you get that score up here, then what do you do?  
A: What?  
M: What do you do once you have the score?  
A: Go to a different one. Because this is like to decide if you want different chips compared to other ones.

Figure 2. Transcript excerpt for chip scores.

is also an example of self-assessment since he felt that 10.78 was not a reasonable score and needed to be larger. In ends-in-view problems such as this one, it is notable that he placed more emphasis on whether the guide worked rather than whether it was “right.” This distinction can be made between designing a tool (the consumer guide) and finding an answer to a problem.

During later testing of the tool, he noticed that the Gourmet Herb chips that none of the students liked, including Alex, had a higher score than the Crunchies Chips. He had been computing scores for the chips by collecting data from the packages and tasting the chips to give a preference score. He was recording total scores for each type of chip at the bottom of the spreadsheet. In the excerpt in Figure 3, the Gourmet Herb chips received a score of 18.

He seemed perplexed that the Crunchies had received a lower score than the Gourmet Herb chips. He then noticed that he had used my taste preference score for the Crunchies and his taste preference score for all of the other types of chips. Before this point, he had not told me that the guide was designed for an individual. Alex seemed to assume that “consumer guide” meant individual consumer guide. Working with a partner may have helped him to develop a guide that would incorporate data from more than one person at a time. However, at this point, it also is not an unreasonable assumption that an individual may generate a guide and score chips. The excerpt also illustrates how during model-eliciting activities students need to grapple with assumptions related to the context and clarify those assumptions for users of their products. Real-world consumer guides typically include explanations of the variables and methods used for generating rankings of products in order to increase their validity and reliability to consumers.

A: They got an 18. They beat the Crunchies.  
M: They beat the Crunchies.  
A: But this is your preference. I liked the Crunchies.  
M: I gave the Crunchies a 4.  
A: What?  
M: Oh. What happens then? Like if you have a different preference than I do.  
A: Well it's supposed to be all from one person's preference.  
M: Oh. So it's an individual consumer guide?

Figure 3. Transcript excerpt for preferences.

Other consumer guides could use iterative processes. For example, a guide may use pairwise comparison of chips in order to find the “best” snack chip. Two types are compared and the “winner” moves on to the next pair to be compared. In addition, stochastic processes may also be used to break ties between types of chips. Chips may also be ranked by each variable and then the rankings by variable may be aggregated. Rankings by individual variable illustrate how data may be re-represented and then combined. In addition, students may use charts and graphs in order to illustrate characteristics or scores for the chips. Again, alternate representations are typical of real-world consumer guides generated for products from dishwashers to universities.

The *Snack Chip Problem* also asks for a shareable, reusable consumer guide. An important criterion for a successful guide was that it should be useful for judging not only the snack chips available in the classroom, but also other types of snack chips. The consumer guide should also be usable by many different people buying snack chips. The use of Excel to develop the consumer guide increases the shareability and reusability of the tool. It was also easy for the student (e.g., Alex) to modify or generalize the consumer guide. As an extension problem, the consumer guide that the students develop for the *Snack Chip Problem* could be used for either other types of consumer guides (e.g., cars, furniture) or the idea of a guide for comparing different objects could be extended to other statistical applications involving data analysis (e.g. giving grades, generating fair teams). Once students have developed a powerful tool for solving one problem, they should have a tool that will help solve other problems even in other contexts.

### **Areas for Further Research**

This paper has explored one instance of tool design in a model-eliciting activity by a seventh-grade student using a spreadsheet to design a consumer guide. Further investigation needs to be done using this type of tool design problem in order to understand the nature of tool development more fully and the mathematics related to tool design. In addition, the student in this example was solving the problem individually. Model-eliciting activities are usually solved in small groups so further investigation could be done related to tool design by a small group. It may also be important to identify the types of skills (e.g., collaboration, new mathematical skills) that become important when solving ends-in-view problems and model-eliciting activities.

In terms of implications for teaching, there are still questions related to assessment and evaluation that would need to be answered. In particular, how can these types of problem be incorporated into the curriculum and how can the products generated by the students be used to document mathematical understanding? This issue is particularly complex given that this type of problem caters a range of mathematical achievement levels that go beyond traditional mathematical understanding. Namely, the development processes required for designing a mathematical tool go beyond finding the right procedure for solving a problem. The processes include the testing, revising, and refinement processes described above as well as the incorporation of multiple mathematical skills. In addition, once a teacher has identified certain mathematical skills, the question then arises about how to decide what to do next. In the case of the

problem described here, a teacher could continue with the exploration of other statistical concepts or for other methods of data representation. Such instructional decisions may depend on the tools developed by the students as well new concepts the teacher may want to introduce. (For more about sequences of activities and other modeling related problems see Doerr and Lesh (in press).) Classroom discussion of the products may vary depending on the teacher's instructional needs as well.

### Conclusion

Tool design is an area that has not been explored extensively in the middle-school mathematics curriculum. However, it is an area that allows students to use many different types of mathematical skills and to use a variety of different types of abilities. In addition, the students need to understand when and how different skills are needed and analyze work with multiple representations of data (e.g., from the chip bag to the spreadsheet to a chart). Tool design is also an important aspect of many mathematically intensive careers such as business, engineering, and science. Model-eliciting activities and tool design are also areas that incorporate the use of technology in ways that go beyond pure computation. The technology facilitates revision and testing of the tools and adds to the realistic constraints of the problems. Knowing when and how to revise a tool is a skill important in general problem solving and the design of complex products.

# **CAUSAL REASONING IN THE PROCESS OF CONCEPT FORMATION: THE CASE OF LINEAR INDEPENDENCE AND LINEAR DEPENDENCE OF A SET OF VECTORS**

Sonia Hristovitch  
University of New Hampshire  
soniah@cisunix.unh.edu

This study, still ongoing, is a part of a research project (Hristovitch, 2001) which investigates the role of metaphors, analogies and symbolization in students' conception of basic linear algebra notions in the case of linear dependence and linear independence of sets of vectors. The results of that project indicated that along with analogies and metaphors reflecting our everyday life experiences, students bring into mathematics the causal aspects of events and processes taking place in the physical world. In this paper I will focus on students' causal reasoning in the process of concept formation and will argue, based on the evidence from the data, that students' causal interpretations of structural (a-causal) relations in mathematics might become an impediment in learning at a higher level of mathematics such as linear algebra. Further, I will try to initiate a discussion on the role of causal reasoning in the process of concept formation with the aim of making initial steps toward developing a theoretical perspective of causal reasoning in mathematics.

## **Theoretical Perspective**

Using Sfard's (1989, 1991, 1992) perspective on concept formation as a frame of reference, this study explores how students come to construct the notions of linear dependence and linear independence and what the obstacles to students' understanding of these concepts might be. Sfard claims that the process of concept formation begins with operational understanding, viewing a concept as a process, algorithm or action; the structural understanding gradually evolves from the operational by viewing a concept as a static construct or as if it is an abstract object. Further, she argues that the shift from an operational to a structural conception is an inherently difficult process for students in any area of mathematics. The problem is especially acute and worth consideration in the case of linear algebra due to the highly abstract nature of this field; even the learning of its very introductory notions requires a rather structural conceptualization and there is not much room for an operational conception.

It is widely accepted that metaphors, analogies and symbolization are central in the process of constructing mathematical knowledge. Metaphors assist us in understanding abstract formally represented mathematical ideas in terms of familiar, everyday experiences (Lakoff & Núñez, 1997; Presmeg, 1997; Sfard, 1994, 1997). Analogies allow us to understand the structure of one conceptual domain in terms of another (Gentner, 1989; Gentner & Holyoak, 1997; Holyoak & Thagard, 1989, 1997), thus help us in constructing models for theory development and problem solving. The inherently representational character of mathematics (Kaput, 1987a, 1987b) makes it

impossible to consider the process of constructing mathematical ideas without looking deeply into the role of reasoning with symbols in that process. However, the project indicated that aspects of students' spontaneous analogies and semantic interpretations of metaphors and symbols might become an impediment in the shift from an operational to a structural conception.

Drawing upon these perspectives, this study explores the role of causal reasoning in the process of concept formation in mathematics. More specifically, the investigation is guided by the following questions: What is the role of causal reasoning in the shift from operational to structural conception? What is the interaction between causal reasoning and other aspects of the process of conceptualization such as metaphors, analogies, symbolization, and students' ability to justify (or explain) their solutions?

### Methodology

This study employs a qualitative research design that integrates observation, interviewing and written samples. The data was collected in a large Midwestern state university where an Introductory Linear Algebra course for mathematics and science majors was offered every semester in two sections taught by two different instructors. Regular class observations were made starting at the beginning of the semester until the concept of interest was completely covered and connected to the material that followed; the lectures were audiotaped and field notes were taken during every lesson. In the course under observation, the students were presented with two definitions of linear independence and linear dependence: the first, rather informal (operational) definition was introduced at the beginning of the semester; the second more rigorous (structural) definition was introduced later in the semester, approximately one month after the first definition. The following are the definitions presented to the students:

*First definitions: A set of vectors is called a linearly dependent set of vectors if at least one of the vectors in the set that can be expressed as a linear combination of the other vectors in the set.*

*A set of vectors is called linearly independent if none of the vectors can be expressed as a linear combination of the others in the set.*

*Second definitions (Test for Linear Independence): A set of vectors  $\{v_1, v_2, \dots, v_n\}$  is called a linearly dependent set if there are scalars  $c_1, c_2, \dots, c_n$ , not all zero, such that  $c_1 v_1 + c_2 v_2 + \dots + c_n v_n = O$ .*

*A set of vectors  $\{v_1, v_2, \dots, v_n\}$  is called a linearly independent set if there are scalars  $c_1, c_2, \dots, c_n$  such that whenever  $c_1 v_1 + c_2 v_2 + \dots + c_n v_n = O$  follows that  $c_1 = c_2 = \dots = c_n = 0$ .*

Two quizzes were collected from all students – one, after the introduction of the operational definition, and the second, after the structural definition. In addition, two interviews were administered following each of the quizzes mentioned above with a subset of the participants in the study.

The participants of the study were 60 undergraduate students enrolled in this course as part of their major requirements. The number of participants (27 in section 1 and 33 in section 2) and their gender and ethnicity were determined entirely by the current enrollment in the classes. The students enrolled in these sections were asked to participate voluntarily in two interviews and only students who signed the consent form (giving permission for participation) were included in the study – 7 students from section 1 and 5 students from section 2, for a total of 12 students.

For the analysis of the quizzes and the interviews, this study employed grounded theory approach (Strauss, 1987) for coding, categorizing and possible theory saturation.

### Findings

The analysis of the data shows that students exhibit elements of causal reasoning mainly in their responses on the first quiz which was given to them after the introduction of the first rather informal definition of linear dependence and linear independence. For this reason, I will present more elaborately the results of this quiz and, later on, at the end of this section I will make some overall remarks on the results from the second quiz and the interviews. The following are the questions on Quiz 1:

- Q1: What does the following statement mean to you? The set of vectors  $\{A, B, C, D, E\}$  is linearly independent.
- Q2: Let  $\{A, B, C, D, E\}$  be a linearly independent set of vectors. If we remove two vectors from the set, say  $A$  and  $B$ , would the set of remaining vectors,  $\{C, D, E\}$ , be linearly dependent or linearly independent? (Justify your answer)
- Q3: Let  $\{A, B, C, D, E\}$  be a linearly independent set of vectors. If we add a new vector  $F$  to the given set, would the new set of vectors,  $\{A, B, C, D, E, F\}$ , be linearly dependent or linearly independent? (Justify your answer)
- Q4: What does the following statement mean to you? The set of vectors  $\{M, N, K, R, V\}$  is linearly dependent.
- Q5: Let  $\{M, N, K, R, V\}$  be a linearly dependent set of vectors. If we remove two vectors from the set, say  $M$  and  $N$ , would the set of remaining vectors,  $\{K, R, V\}$ , be linearly dependent or linearly independent? (Justify your answer)
- Q6: Let  $\{M, N, K, R, V\}$  be a linearly dependent set of vectors. If we add a new vector  $S$  to the given set, would the new set of vectors,  $\{M, N, K, R, V, S\}$ , be linearly dependent or linearly independent? (Justify your answer)

The responses to these questions indicate that students employ causal reasoning in various situations: when interpreting metaphors, when interpreting the symbolic representations of equations, and when gaining understanding of the novel situations in analogy to prior concepts and experiences.

1. In the definition of linear dependence and linear independence, the phrases “written in terms of” or “expressed as” are used in their literal meaning, signifying that a linear combination is just another representation of an already existing object (vector, matrix, or function). In contrast, the responses in the first quiz show that some of the students (7 students) made sense of the phrase “vector expressed as a linear combination” in terms of their everyday life experience and transformed it into rather metaphorical expressions as “formed by,” “made up,” “comprised of,” “produced,” or “combined to create.” Thus, the syntax of the symbolic representation of vectors expressed as a linear combination was captured by metaphors which carry operational and causal character as well. For example:

(Student C13)

Response Q1: They cannot be comprised of each other.

Response Q5: Dependent. They are still dependent because they would not be affected by removing M and N from the set.

Response Q6: Dependent. A vector in the set can still be comprised of a combination of the other vectors in the set.

(Student B29)

Response Q1: One of these or multiple of it cannot be added to a multiple of another vector in the set to produce a third vector in the set. Or a multiple of one vector can equal another.

Response Q3: This depends on what vector F is, if F completes a linear combination with one of the existing vectors, the set is linearly dependent. Otherwise, the set remains linearly independent.

The students viewed “vector expressed as a linear combination” as a process in which a vector is “made up” out of the other vectors in the set as if they are its “components.” In these examples we see how a static structure is viewed as a causal-like process of building up or constructing and, depending on the outcome of these constructions, a set of vectors might “become” dependent or independent. We should notice that the second student (B29) used the term “produced” rather metaphorically and this production-like view of “vector expressed as a linear combination” did not affect negatively his/her inferences. On the other hand, this same view (“comprised”) might have led the first student (C13) to wrong conclusions in question 5.

Further, in the context of the definition, the words “independent” and “dependent” are used metaphorically, indicating only the relational character of the concepts of linear independence and linear dependence. When interpreting the definition of linear independence, some students (4 students) deepened the perceptual roots of the metaphors “dependent” and “independent” and transferred into the area of mathematics a

sense of causality – “vector is affected by,” “the vectors depend for their values” or “you can’t do anything with one without knowing the others.” The following examples show students’ semantic interpretation of the “dependent” metaphor.

(Student C10)

Response Q4: The vectors rely on each other to exist.

(Student C5)

Response Q4: That means that all of these vectors depend on the others for their values.  $c_1M + c_2N + c_3K + c_4R = V$  or any combination of terms. You cannot find one without having information about another.

(Student C19)

Response Q4: M, N, K, R, V depend on each other. You can’t do anything with one vector without knowing the others.

(Student C18)

Response Q4: Means, each vector is dependent on the others. By changing one will affect the rest.

The students deepened the perceptual roots of the metaphors “dependent” and “independent,” and transformed them into “rely on each other to exist,” “depend on the others for their values” or “you can’t do anything with one vector without knowing the others.” The intention of these metaphors in the context of mathematics is to bring to the fore the implicit structural relations (the ground) in a set of vectors. The students though, influenced by their everyday life understanding of the words “dependent” and “independent” brought up an unintended meaning of the idea of relation carrying the flavor of causality. And again we observe, just as in the case of “written in terms of,” the operational, process-like, causal character of students’ understanding in the initial phase of conceptualization of the notion of linear dependence and linear independence.

2. The responses on this first quiz also show that, for some students (12 students), the understanding of linear independence and linear dependence develops in analogy to their prior experiences with sets and everyday life settings that resemble the novel situation they are faced with. In analogy to their experiences with material sets, some students reduced linear independence and linear dependence from a relational property of a set to an attributive property of individual vectors, viewing individual “dependent” and “independent” vectors as causal *carriers* or *agents* of the set property. Respectively, in some instances, a vector that can be expressed as a linear combination of other vectors was called “dependent” and a vector that cannot is called “independent.” As a result, for 5 of these 12 students a set of vectors was expected to be dependent if each vector in the set is “dependent,” and consequently wrong infer-

ences were made. In this way, a property of a set was reduced to a property belonging to each individual element of the set, and instead of useful analogy we were witnessing misanalogy with consequent wrong inferences. For instance:

(Student C10)

Response Q1: None of the vectors rely on the others to exist.

Response Q2: They would be linearly independent. They were independent before the others were removed, and the removed ones are independent.

Response Q3: We do not know because we were not told whether F was dependent of any of the other vectors.

Response Q4: The vectors rely on each other to exist.

Response Q5: Linearly dependent because they were to start with and the ones removed were also dependent.

Response Q6: Not sure, S might be independent the others still dependent.

In this example, linear dependence was interpreted as “vectors rely on each other to exist,” which suggests that the student, although misinterpreting the definition, did not ignore completely the relational character of the concept. Nevertheless, from the responses on the other questions, it is evident that, in analogy to sets of concrete objects, the student considered *independence* or *dependence* of set as a property of individual vectors (“the removed ones are independent”; “S might be independent”) and expected a set to be dependent or independent if each vector in the set is respectively “independent” or “dependent.” From the response on Question 5, it is evident that the student viewed each vector in the initial set as “dependent” and respectively, without any considerations for possible linear combinations among K, R and V, the set of remaining vectors was qualified as “dependent” because “they were to start with.” Further, we should notice that in Question 6 the student referred to vector S as “might be independent” without reference to the set to which it was supposed to be added. Respectively, because the others are “still dependent,” the new vector was never actually joined to the initial set and the new set was not considered. Thus, we can infer that, in analogy to material sets the students considered individual vectors as carriers or agents of the property of a set and developed the following model: A set of vectors is independent if none of the vectors in the set is “dependent” on the others; A set of vectors is dependent if each vector in the set is “dependent” on the others. The fact that the first statement is true but the second false further complicated students’ difficulties since for independent sets, the analogy to the material sets worked; for dependent sets, however, the analogy did not.

Further, 4 of the 12 students were realizing that for a set to be dependent not all vectors should be necessarily expressed as a linear combination, and that it is enough

if “at least 2 vectors from the set  $\{M, N, K, R, V\}$  are linearly dependent.” In other words, in accordance with the definition of linear dependence, the students modified their everyday life experience to suit the novel situation they were faced with. The new model allowed them to give a correct answer to all of the questions, and the analogy to sets of concrete objects was indicated only in the ways they phrased their responses, specifically in the use of the terms “independent” and “dependent” in reference to individual vectors. The arguments were abundant with phrases like “if all five were independent” or “at least one is dependent.” Such phrases, and especially the often used expression “if M and/or N were the only vectors dependent in the set,” are indications for a mapping between material sets and sets of vectors – the notion “vector expressed as a linear combination” is viewed as if it is a property of individual vectors. Because of the alteration, made in accordance with the definition of linear dependence (shifting from “each” to “at least”), the model developed by the students worked despite the focus on individual vectors. The student obtained correct answers on question 5 after removing the “only dependent” vectors, making possible that the “remaining 3 would be independent,” and respectively, if one of the remaining is dependent on the others the “remaining three will be still dependent.”

For one of the students, however, despite the modification in the definition of a dependent set (see Response Q4 in the example below), the analogy to sets of concrete objects led him/her to an erroneous response on question 5.

(Student C13)

- Response Q1: Each vector A, B, C, D, and E belongs to its own vector space. They cannot be comprised of each other.
- Response Q2: Independent. If  $\{C, D, E\}$  are independent with the set of  $\{A, B, C, D, E\}$  then by removing a, and b it will not affect their independence.
- Response Q3: That depends on whether or not F is a vector dependent on any of the others in the set. If F is dependent then the set would be dependent, and vice versa.
- Response Q4: A vector in the set  $\{M, N, K, R, V\}$  can be made up of a combination of the other vectors in the set.
- Response Q5: Dependent. They are still dependent because they would not be affected by removing M, and N from the set.
- Response Q6: Dependent. A vector in the set can still be comprised of a combination of the other vectors in the set.

Although locally (only in question 5), the student fell back to the understanding of the students in the first group (shifting back from “a vector” to “each”). Respectively,

in his/her response there are no considerations of the possibility that the vectors K, R, and V might be unrelated in the new set – the vectors in the new set are “still dependent because they would not be affected by removing M, and N from the set.”

Finally, some students (3 out of the 12) used slightly modified version of the analogy to material sets – they did not transform “vector expressed as a linear combination” into a property of an individual vector. Instead, they reduced the participation in a linear combination into a permanent (attributive) property of individual vectors even when a vector participates in a combination with a zero coefficient. Thus, those students considered the participation of a vector in a linear combination as the *carrier* or the *agent* of the dependence of a set. For example:

(Student B9)

Response Q1: Any given vector in the set of {A, B, C, D, E} cannot be written in terms of the other 4 vectors. There would be no way to manipulate them such that this would become true, even using 0's.

Response Q2: Linearly independent. If all 5 original vectors could be written in terms of each other, than any given group of the 5 could also. Since {A, B, C, D, E} is independent, so is any subset.

Response Q3: Linearly independent. If the set of {A, B, C, D, E, F} were linearly dependent, then that would force {A, B, C, D, E} to be linearly dependent.

Response Q4: Any given vector in the set can be written in terms of the other 4, using 0's if necessary, but two have to have non-zeros.

Response Q5: Dependent. If two vectors are removed, one may manipulate the equations so that the other three can be written in terms of each other.

Response Q6: Dependent. Even if S is unrelated, a 0 constant may be multiplied to it.

The above example illustrates this permanence of the participation in a linear combination. In the response on question 3 the student employed indirect reasoning erroneously to show that assuming the new set to be dependent will lead to the contradiction that the initial set is also dependent, completely ignoring the possibility of having a relation between the vectors in the new set. In other words, the ability to participate in a linear combination was considered to be a property of the individual vectors despite the changes in the set. Similarly, the response on question 3 suggests that in the student's view, even if two vectors were to be removed from a dependent set, “one can manipulate the equations so that the other three can be written in terms of each other.” Thus, for the students, the participation in a linear combination is con-

sidered to be a permanent property of the individual elements of a set. Just as with the members of a team, even when some of them do not play at a given moment (“having a zero coefficient”), they are still members of the team.

3. When dealing with the problems in this quiz, students (38 students) focus their attention on the added and the removed vectors as a cause for the outcome without considering the new set as a whole – “if the removed vectors are dependent”, “if the new vector is dependent itself” – as a result, wrong inferences were made.

(Student C18)

Response Q5: The remaining set will still be dependent. K, R, V were some how related to M, N. Therefore, removing M, N will affect the value of K, R, V.

(Student C22)

Response Q3: Not sure, you would have to check for the dependence or independence of F compared to the other vectors.

Response Q5: Could be either. By removing M & N you might be changing the dependency of the vectors to independent if M & N are the same or a multiple of {K, R, V}.

(Student B17)

Response Q3: It could be linearly independent or linearly dependent because it is possible for some linear combination of {A, B, C, D, E} to be equal to F. However, it is also possible for F not to be dependent of {A, B, C, D, E} as well, making it independent.

Response Q5: I could be either independent or dependent, depending on whether or not M & N are needed to form {K, R, V}.

As evident from the above examples, students attempt to achieve coherence of their explanations by trying to identify the reason (or the cause) for the status of the new set – in their justifications they focus on how the addition or the removal of vectors and respectively the properties of these vectors might lead to a “change” in the dependence or independence of the new set. This attention to the added or removed vectors as a cause for “maintaining” or “changing” the status of a set further indicates the operational character of students’ understandings of linear dependence and linear independence at this stage.

Finally, I would like to make some remarks about the findings from the interviews and the second quiz. The responses on the questions in the first interview support the findings from the first quiz that some students (3 out of 12 interviewed) intuitively understand linear dependence in analogy to sets of concrete objects; and without paying much attention to the precise formulation of the definition, they transform “at

least one can be expressed” into “vectors are dependent on each other” or “all of them are dependent on,” thus, viewing the “dependent” vectors as causal carriers of the property of a set. The data from the second quiz and the following second interview does not provide much evidence for causal reasoning in the students’ considerations. This should not lead us necessarily to the conclusion that the students have discarded causal inferences after the introduction of the structural definition, neither that they have shifted to structural understanding of linear dependence and independence, but rather that the structural character of the questions asked did not provide much room for employing everyday life intuitions. In the process of learning, the initial intuitions of some students gradually evolve towards a more structural understanding of linear independence. But I should point out that on the continuum between operational and structural understanding, only 10 students consistently exhibited structural understanding across all the problems given in the second quiz. Most of the students (40 students) remained with a rather operational conception, applying the structural definition occasionally and often not successfully. Some of them (12 out of 40) developed a procedural understanding of linear dependence and independence. They transformed the second definition into an algorithm of finding the row-reduced-echelon form of a matrix, but were unable to apply the test in more abstract and complex situations. Finally, I should mention that 10 students did not grasp the notion of linear dependence and experienced difficulties in applying both definitions.

### **Discussion and Conclusions**

As pointed out earlier in this paper, metaphors and analogies are vital for the process of concept formation – they assist us in grasping abstract mathematical ideas in terms of familiar everyday life experiences and allow us to gain understanding of the structure of one domain in terms of another. But it is evident from the results of this study that the use of metaphors and analogies in the area of mathematics is not unproblematic. Most mathematical definitions contain metaphors which have to be interpreted by students in order for the concept behind the definition to be understood. In the definition of linear dependence and linear independence, the metaphorical expression “dependent” when applied to a set, although having everyday life perceptual roots, intends to explicate the notion of “relation” (that there is a relation among the vectors in the set). When interpreting the definitions, specifically the terms “dependent” and “independent,” students, influenced by their everyday life experience, deepen the perceptual roots of these metaphors and transfer into the area of mathematics a sense of causality: “vector is affected by,” “the vectors depend for their values.” Further, the focus on “vector expressed as a linear combination” in the operational definitions might have fostered students’ everyday life intuitions to view such vectors as the “carriers” of the dependence of a set. As evident from the results on the analogy to sets of concrete objects, these intuitions led some students to view individual vectors as “dependent” or “independent,” and others students, to transform vectors’ participation

in a linear combination into a permanent property of the vectors; thus encouraging the view that a set is dependent if each vector in the set is “dependent” or if each vector participates in a linear combination. As a result of these interpretations students made inappropriate inferences in several occasions. Thus, students’ interpretation of a metaphor depends greatly upon students’ understanding of the established ‘norm’ of language usage in the area of mathematics. Distinguishing between what is literal and what is metaphorical in the mathematical language amounts to understanding the nature of mathematics which leads us to the question: Is mathematics susceptible to causal explanations and causal agency? In the literature on philosophy of science and mathematics there are many rivaling theories about the existence and the cognizing of abstract objects. But despite that there is no leading epistemology that gives coherent and persuasive account of such objects, there is still some consensus on the view that mathematical objects are abstract and causally inert (Shapiro, 1997; Bunge, 1959) and that explanations in mathematics are outside the *causal nexus* (Kitcher, 1989). Thus, in the area of mathematics there are no “agents” or “carriers” of special properties, so whenever in mathematics we talk with language holding such meanings, it is only metaphorically.

But the ambiguities in interpreting metaphorical expressions cannot account for all the difficulties that students experience in the process of conceptualization. Students’ analogy to sets of concrete objects has deep roots in their everyday understandings where the constitution and the properties of a set depend primarily on the common attributes of its individual elements. In a study of learning group theory, Dubinsky (1994) reports a similar phenomenon: students, ignoring the operation involved, “interpret a group primarily in terms of its elements, that is, as a set” (p. 273). In his view, it appears possible that students are assimilating the problem situation to an existing set schema.

In this study, in the case of linear dependence, students do not ignore the relations among the vectors in the set, but transform them as if they are an attributive property of each individual vector, thus the “dependent” vectors are viewed as the “carriers” or the “agents” of the dependency of the set. Students’ difficulties in dealing with relations among the elements of a set might also be due to difficulties in shifting between distinct ontological categories (Chi, Slotta, & Leeuw, 1994). In their theory of conceptual change, Chi et al. (1994) claim that learning is difficult if students have to shift from initial understanding of a concept as belonging to the ontological category of “Matter” (sand, paint, human being) to an understanding of the concept as belonging to the category of “Processes.” The shift could be especially difficult when the new understanding belongs to the subcategory, “Constraint-based-interactions,” which are processes with no material causal agents (such as magnetic field and gravitational field). This perspective partly explains students’ focus on individual vectors in the analogy to sets of concrete objects and their expectation that each vector in a depen-

dent set is a “carrier” of the dependency, either by being “dependent” or permanently caring a participation in a linear combination. Students’ early understanding of sets (or of collection of objects) originates in their everyday experiences with sets of concrete objects where the constitution of a set is usually determined by attributive properties carried by each material object in the set. Thus, for some students the transition to understanding a property of a set based on algebraic relations among the elements of the set, i.e., with no material carriers, could be very difficult. In fact, such difficulties can be experienced even by experts: for example, for years physicists were searching for a magneton, a material carrier of the magnetic field, or a graviton, a material carrier of the gravitation field.

Thus, in the process of learning new mathematical ideas, students attempt to achieve coherence and consistency in their understanding by grounding these new ideas in prior mathematical and everyday life experiences. But, as evident from the above findings, these prior concepts and ideas, although enhancing students’ understanding at a certain level, they can hinder the shift from operational to structural conception and become an impediment in learning mathematics at a higher level.

# **FRactal Filaments: A Simile for Observing Collective Mathematical Understanding**

Thomas Kieren & Elaine Simmt  
University of Alberta  
tkieren@telusplanet.net

This paper provides one response to the questions of the nature of and the portrayal of collective mathematical understanding, particularly as it might be observed in a classroom context. The view here considers collective understanding as an embodied, dynamical phenomenon portrayed using the simile of fractal filaments. Using the responses to a prompt by students in a third grade classroom (8 year olds), such a fractal and entailed fractal filaments are observed to be about patterns drawn from the actions and inter-actions of students as they engage in mathematical thinking. It is shown how self-similarity across scale and recursion, two key features of fractals, figure in the observed dynamical collective understanding. Some characteristics of this understanding include common constructive mechanisms and mathematical interpretation. As well as complementing recent work on dynamical personal understanding and on social interactions and mathematical knowing, the paper points to the usefulness of this view for teachers interested in observing and acting upon the dynamical collective understanding that emerges in their mathematics classes.

There has been considerable recent research on the relationships between various classroom interactions among the members of a mathematics class and the knowing acts of the individuals (Cobb, Yackel et al. over the past 10 years (e.g., Cobb, Boufi, McClain, & Whitenack, 1997); Goos and Galbraith et al over the last 5 years (e.g., Goos, Galbraith, Renshaw, & Geiger, 2000)). This paper discusses work and ideas that complement such approaches. It relates to a question raised at PME-NA by Martin (2001) of the possibilities for and the nature of collective mathematical understanding. Over the past 15 years Pirie and Kieren have been developing and using a theory in which mathematical understanding and its growth are understood as dynamical personal phenomena (e.g., Pirie & Kieren, 1994). Such Dynamical Personal Understanding (DPU) is observed to occur in action and inter-action. However, it is not simply about such action and inter-action per se but is about patterns in that action which are observed as varying modes of less formal and local or more formal and abstract understanding. If understanding is seen as a dynamical personal process then the question of collective understanding is problematic. What is it? How does it arise? How is it related to individual acts and social interaction? How might it be observed and or used in a classroom by a teacher or researcher? It will be the purpose of the proposed paper to explore the concept of collective mathematical understanding by observing it using the simile of a "fractal filament."

## **Theoretical and Observational Frames**

The observational ideas in this paper related to Dynamical Collective Understanding (DCU) are inspired by a number of recent ideas about knowing, such as

emergence, coemergence and dynamical systems. The particular observational simile, fractal filament and related consequences, will be posed within what Maturana would typify as objectivity-in-parentheses; that is, this observational frame and related ideas are part of a multiversal rather than a universal perspective (Maturana, 1988; Bohm, 2000).

We turn first to the idea of collective intelligence through emergence. In a recent book, S. Johnson (2001) reviews recent research showing how observed collective properties can be characterized as emergent from individual acts. For example, efficient ant colony food retrieval can be seen to emerge from repeated individual acts of ants based on 3 elements: ants' capability to make certain bio-chemical distinctions; trace pheromones of ant activity; and opportunities for ants to bump into other ants or their traces. Perhaps collective understanding can be observed as such an emergent, or we suggest, coemerging phenomenon.

If this is so, then collective mathematical understanding, taken as a dynamical and plastic phenomenon, will be observed to occur in the mathematical actions and particularly in the inter-actions of persons. This stance would be congruent with considering DCU as an emergent property. But DCU is not simply about actions with associated dynamical personal understandings or simply reflected in the nets of interactions among such persons in action. Like Kaufmann's (1995) idea that life is observed in patterns drawn out of the autocatalytic nets of molecules, DCU is observed in the patterns in the actions and inter-actions among knowers. Thus, DCU is observed in, and in fact is embodied in, inter-actions such as co-occasioning and conversation; DCU is about patterns in these and not properties of them per se. DCU is of a different implicate order (Bohm, 2000) from them, related to the whole collective and its total embodied setting rather than referenced to individual knowing per se.

However, as suggested, DCU can be observed to occur in settings where individuals are acting and inter-acting. Based on enactive views of cognition derived from the work of Maturana and Varela and some of our previous related research, we posit that one can *observe collective understanding* as a dynamical process emerging, in Johnson's (1987) sense above, from individual knowing acts based on three conditions: the individuals' capabilities for making certain distinctions which the observer sees as mathematical; observable re-presentations of such actions; inter-action among such individuals and with the environment, which includes the culture of the communities in which the persons in interaction are observed to exist (e.g., the culture of the particular classroom, the broader culture of historical and contemporary mathematics). Mathematical knowing and the related phenomena of personal and collective understanding are taken to be a 'bringing forth of a world of significance including mathematics' (Maturana and Varela, 1992). Such knowing, as well as DPU and DCU, coemerge in interaction with the environment including others such as other students, teachers and materials. Our understanding of this is illustrated by the model in Figure 1 (Simmt, 2000; Simmt & Kieren, 1999).

Figure 1. Knowing in interaction.

This diagram allows us to observe both the individual determinants and the social/environmental co-determinants of knowing all-at-once. Such knowing and the related understandings are observed then as coemerging phenomena. Following the various paths in this model suggests one can observe knowing from a constructivist or a social constructivist view depending how the influence of the environment on the individual is taken. Another feature of the model is important for the thinking in this paper. The knowing actions and representations of the individual can be observed as occasions for the understanding acts of others (for example, other students, the teacher or the researcher). These actions and representations also can occasion changes in the environment (for example, the ways in which the tasks or materials or mathematics is interpreted). It is in this way that the cognitive domain can be observed as enhanced through interactions (Maturana, 1991; Simmt & Kieren, 1999). As well, it is in this way that the DCU can be observed to emerge from and coemerge with individual understandings and interactions among the persons enacting them. It may well be that DCU can be observed as a feature of this plastic cognitive domain. As such it can be observed to occasion DPU as well as be seen as arising in a space of interacting individuals.

If we observe dynamical collective understanding in a setting what do we 'see'? Our suggestion is that if we take the model above and use it to interpret mathematics knowing in action then we note that collective understanding arising as above is like a 'fractal filament'. Assume that a fractal filament is a subset of a fractal object. The fractal may be thought of as a collective of connected nodes. Like the pieces of art which Peitgen (see Peitgen & Richter, 1986) derives from the Mandelbrot set, each node has its own character; yet each node is in some way similar to the others and, the entire Mandelbrot set demonstrates self-similarity across scale. While each filament of a fractal has its own character and look, yet each has critical features of the whole and can be seen as arising through a similar dynamical process. We are observing collective understanding in this way.

Why might we do this? We are viewing collective understanding as a dynamical, changing phenomenon. The model of knowing we are using observes such knowing both for the individual and the community in which it occurs as a recursive phenomenon. Fractals have been used in many places to characterize such dynamical recursive phenomena. Thus we are using it as a simile.

### An Illustrative Sketch from Research

The following sketch is taken from the observation of children in an 'average' 3<sup>rd</sup> grade classroom of 8 year olds in a western Canadian city. It is from one site of an ongoing interpretive research programme being carried out using varied data sources from multiple sites. A feature of this research program is that data are collected and interpreted by several researchers and reinterpreted in an ongoing and recursive manner. In the class from which this illustration is taken, the children are coming to know fractional numbers. They have previously worked with such numbers that can be shown by fractions with denominators that are powers of 2. The children have observed and used the multiplicative proportional character of fractional amounts through the use of paper folding and related informal mathematical activities. In the work here they are looking at fractional numbers as 'muchnesses' emphasizing their additive character. One day earlier they had been introduced to a 'half fraction kit'—a set of inter-related rectangles such that they have 2 units worth of ones, halves, fourths, eighths and sixteenths (a subset of the 'half fractions'). Each of the children has a kit. The children work in groups of 3 to 5. It is the classroom practice of this teacher to have children illustrate their work for the whole class. Thus while each child creates her or his own 'solution(s)' they are also in direct contact with others in their group and there are many examples of work and other students' explainings available. As will be seen below, the children or at least nearly all of them are capable of making distinctions in fractional number settings (e.g. can work with fractional amounts as 'sums' of other fractional units; can transform units into other units); they are encouraged to make and do make observable re-presentations of their ideas in many and variously public forms; they do interact with one another and with elements of the environment in a community with an observable mathematical 'culture'.

The students are working from a prompt, *Missing Fraction Mysteries*: "A fractional amount is missing or hidden. We know it is more than  $1/4$  and smaller than  $3/4$ . What might it be?" Quickly, nearly all (except two) of the students generate multiple 'solutions' to the 'mystery'. Most of the children exhibit individual Image Having dynamical personal understandings (Pirie & Kieren, 1994). That is, such children are seen to be able to construct a fractional quantity that matches the constraints of the mystery in some without being given explicit directions of how to do so and without having to observe the missing amount. In other words, they have an image of fractional numbers as additive amounts. Further, they are observed to produce numerous re-presentations and representations of their thinking. Finally, there is opportunity

for significant student-student; student-teacher; and student-environment interaction as anticipated in the interactive knowing model above. Conditions are in place for observing the possibility of emergent collective understanding.

What is observable? Three sets of responses are illustrated here. There are many more pieces of the children's work that could be fitted into these sets, particularly the first one. Further, although each piece of work noted comes from a different child various of these children's works and those of many others would be classified in more than one of the three sets illustrated here. Thus the actions and the understanding in action of any child are not necessarily unique to one of these sets or any other set not here illustrated.

The illustrative set A-D represents only a small fraction of the individual understanding acts that could have been associated with it.

- (A) Teanna solves the problem by laying a half-piece, an eighth-piece and a sixteenth-piece on top of three fourth-pieces and says "there".
- (B) Sally (in Teanna's group) lays down a half-piece a 3 sixteenth-pieces, writes  $1/2 + 3 \ 1/16$  [sic]. She notices that this is just  $11 \ 1/16$  [sic], which the students, in chorus, shout is "just one sixteenth from three fourths".
- (C) *In another working group Donny is sent to the board with his solution  $1/2 + 1/8 + 1/16 + 1/32 + [ \dots ] + 1/1024$  which he writes out and draws showing a very tiny rectangle as the difference from  $3/4$ .*
- (D) *Quickly both members of his group and more than 5 others make up solutions which resemble but are not like Donny's.*

At one side of the room three children, two in one working group and one in another group, interact (E-H).

- (E) *Trying to be different Dane writes  $5.9/8$ .*
- (F) *One of his partners, Wally sees this and writes  $5.99/8$  and says "that's just a hundredth off" [of  $3/4$ ].*
- (G) *Megan eyeing their work from the next group writes  $5.999/8$ . When asked about it she doesn't know the name of the decimal fraction she has written but she says her solution must be even closer to  $3/4$ .*
- (H) *Soon the three of them are representing many fractional amounts such as  $5.999999/8$ . Notice that unlike the children in A-D, these children make no direct or even reference to the half fraction kit pieces in these actions.*

One of the members of Donny's group Sam starts a different kind of work (I-J).

- (I) *Sam takes a one-unit piece and places a fourth piece on one corner of it. Just adjacent to this piece he places a sixteenth piece. He draws a sketch of this*

*and writes  $1 - 1/4 - 1/16$ . Like Donny he also does a like drawing and writing at the board.*

- (J) *Many other students and some whole working groups of students are forming solutions like Sam's and many are writing subtractive sentences like his.*

### **Observing Collective Understanding Using Fractal Filament as a Simile**

It can be observed that the children above are engaging in mathematical actions and interacting about them. It has been shown that they are enacting various kinds of dynamical personal understandings (DPUs). But what might we make of Martin's question of collective understanding? How might observing A-J or each of the sets above in fractal terms help us observe and understand the dynamical collective understanding? If we try to interpret the collective understanding of at least A-J above as fractal-like then there should be some features of it that are self-similar across scale. That is, the collective understanding of the whole should have features that manifest themselves, perhaps differently in the three sub-filaments.

Some features of this dynamical collective understanding might be:

- I) Common cognitive mechanisms: enacting fractional amounts as additively combinable units. This feature may emerge from the individual knowing structures and DPUs. Might we think of part of the collective understanding as this common approach to the fractional quantity?
- II) Common form of language use: descriptive and analogical language use. Although the children use fractional symbols and language in ways that an observer would interpret as appropriate, this language use while certainly generative especially in filament E-H is descriptive and analogical in form; the symbols are put for other kinds of quantitative actions. Where additive symbols are used, the children, although many can, see no need to actually 'do' the addition. Further the children make inventive but grammatically and mathematically appropriate use of symbols. While language use and its related metaphors have a personal basis what we are noting here is that this form of language use is occasioned by the collective.
- III) Common mathematical interpretations: in each of the individual acts characterized above and in each of the sets one can see that all of the 'solutions' to the mystery are amounts which are close to  $3/4$ . Of course there is nothing in the prompt or the materials that demand such a solution. But it appears to be just the way "they see it and act on it." Could this be part of a *collective image having*?
- IV) Occasional commonality: actions are occasioned by the kit and interactions. To an observer it appears that the whole class expects to learn mathematics from using materials or from observing the work of others. As the individual

differences in the work above illustrate, individual work is not caused by the materials or teacher expected responses or by the work of others; the individuals appear to select elements from the rich sources on offer and transform them for their own use. Such occasioning appears to be an expectation of the participants in this community and we conjecture is a feature of the DCU.

These and other features might be used to form part of the characterization of the group's collective understanding. It is important to note that none of these features was explicitly discussed in class or by any of the groups themselves. Certainly none of these features were 'taught'. But they can be observed and in that observation can be taken to emerge through and coemerge from the knowing and understanding actions individuals, the re-presentations available and the inter-actions or 'bumpings' which occurred. Further if one looks at A-D; or E-H; or I-J each these features is present in these filaments as well, of course in very different forms. One can contrast the kinds of symbols used in each filament but also see the common informal nature of the language use as well as the commonness of mathematical interpretation and additive nature of the solution. Thus these emerging features of DCU can be seen as features of self-similarity across scale or across sub-filaments.

There are many ways in which collective mathematical understanding might arise or emerge. The fractal filament simile suggests that collective understanding might be observed as a recursive phenomenon or might arise recursively. In what ways, if any, is this the case here? It is clear that the re-presentations of earlier understanding actions are available to the individual, to members of each working group, and at least in some cases to the class as a whole as 'input' to later work. Further there is evidence that interaction as anticipated by the Simmt model occurs particularly in the filament E-H. That is actions of individuals and their re-presentations are not only observed as occasioned by others and the environment, but the actions of individuals can be seen to occasion actions in the group and change the environment (that is the task in that group is at least temporally a task about decimal fractions approaching six. The filament E-H offers a further illustration of self-similarity with the whole but with a different language emphasis. After creating a number of solutions similar to those in A-D, Dane deliberately tries to be different (E). Notice in E that the use of decimal in a ratio form is very different from A-D but yet shares the commonalties I-IV. Wally (F) is observed to be occasioned by Dane's representation but certainly does not copy it. Megan enacts an understanding (G) that carries further what she sees to be Wally's contribution to what is now a decimal interpretation of the original prompt and acts to initiate a continuing co-occasioning of mathematical actions in their group (H). The new actions recursively build on hence also change the interpretations of the previous understanding actions both mathematically and socially in the community. Dane's earlier "showing off" now becomes a part of the actions which underlie the collective actions E-H. Thus such features of emergent dynamical collective understanding is

*contingently observed* be a recursive phenomenon maintaining its central character yet undergoing continual change. To an observer, the cognitive domain for the class is changing as well. That is the possibilities for personal cognitive, the mathematical, the linguistic and the social elements of knowing are changing for the collective and the features of DCU might be seen as elements in that dynamical cognitive domain.

While the collective mathematical understanding is observed here as a phenomenon of an implicate order, it can yet be seen as fully embodied in the collective, here the collective of the class. Because the collective is composed at another level of individuals the collective understanding is embodied in a personal structural sense in that as suggested by the Simmt model in Figure 1, individual knowing actions raise the possibility of occasioning changes in others and hence in the collective and hence collective understanding. But as seen particularly in feature IV DCU is also socially embodied just as changes in it emerge from inter-actions occurring in a mathematical/social milieu. Finally, DCU is observed as mathematically and culturally embodied. It is particularly evident that the elements of practice in this classroom provided a useful research environment in which to observed both growth in DPU and DCU. Such collective understanding can be seen both as related to and recursively contributing to the living culture of the mathematics classroom. At the same it also is a vestige of the historical and contemporary communities of mathematical practice.

### **Consequences of and Possibilities From this View of Collective Understanding**

In mathematics, fractals can be observed as markers of dynamical, recursive dynamical systems. One might then expect fractal features in observing collective mathematical understanding as a dynamical co-emerging phenomenon. We have tried to show in what ways the simile of fractal might be useful both in observing and in characterizing collective mathematical understanding. In particular we have tried to show just how features of this collective understanding might arise recursively and manifest themselves in a self-similar manner across sub-collectives or sub-filaments. Using this simile raises different research questions about collective understanding only a few of which are: In particular settings what are the characteristics of collective mathematical understanding? What are the similarities and differences in the collective understandings of different classes perhaps engaging with similar mathematical topics or curricula or similar prompts or tasks? In what ways are the qualities of the collective understanding of a particular class different depending on the curricular topic or the prompt offered? In what ways characteristics both of the individuals, the interaction and the classroom culture give rise to or support the collective mathematical understanding? What might be the nature of Collective Primitive Knowing as a basis for Dynamical Collective Mathematical Understanding? In what ways does the collective understanding or features of it occasion individual understanding in particular settings?

But using the concept of fractal filaments as an observational tool has consequences for teaching as well. First, it might possibly provide teachers with a tool to observe the mathematical understanding of their classes in a dynamical on-going manner. Using such a tool means that the teacher is made more aware at a class level of the recursive character of mathematical knowing and understanding. The teacher can also be aware of the features of collective understanding at a quite different level and character from individual understandings in action. Further she can become aware of the different manifestations of this understanding in the student actions underlying different filaments. For example, in this case the teacher might become more aware of the general features of the informal language use in the classroom and build this knowledge into her patterns of interacting with the class or various working groups in it. It might also prompt her to observe how the use of language changes over time and hence how this feature of collective understanding changes. Because the teacher is both a leader of and part of the collective in the classroom, she can use her observations to change her perception of mathematics as occurring in her classroom or of the nature of the mathematical task or prompt as lived out in the actions and inter-actions in her classroom, but also to change elements of classroom environment in ways that she thinks might affect the collective understanding. For example, the teacher in the setting discussed here might have reposed the prompt in such a way as to change the collective understanding that the solution must “approach” three fourths as a bound. More generally, if collective understanding is a coemerging feature of a self-organizing system, the teacher might be prompted to probe her role as both a learning member of that system and as a special ‘catalyst’ in it. This raises the broader question of the roles and effects of the teacher and the external and the lived curriculum on the collective understanding of a class.

In response to a question about the nature of and the characterization of collective mathematical understanding from Martin (2001) we have suggested using fractal filament as a basis for observing such understanding. The basis for the use of this tool was derived from recent ideas in emergence, self-organizing systems, and knowing as coemergent. Using the tool enabled us to observe features of collective understanding that arose under particular conditions in one classroom. The questions raised above suggest that further study of collective mathematical understanding may be interesting and useful persons interested in mathematics knowing and understanding in action, in the relationship of socio-cultural classroom features to such knowing as well as those interested in different approaches to thinking about the role of teachers with respect to the changing understanding in their classrooms.

## REMEMBERING AND FORGETTING IN THE MATHEMATICS CLASSROOM

Students often have difficulty in transferring their mathematical knowledge into new situations. We offer one explanation for this phenomenon, by exploring the ways in which a group of students came to know about ideas of similarity in the context of a problem-based curriculum and contrasting how they acted when facing a new problem that might appeal to their knowledge of similarity. We hypothesize that lack of transfer into some novel tasks is a byproduct of the actions by which instruction organizes a public memory oriented toward transfer into a range of familiar tasks.

Among the suggestions for problem solving that Pölya (1948) provides in *How to Solve It*, a notable one is that of creating a “plan,” considering one’s previous experiences. The suggestion triggers the image of searching through a mental filing cabinet of past experiences, where all related problems have been labeled and organized, and using that data to inform attempts at the task at hand. But it is not so simple. Whereas searching for past experiences to plan and attempt novel tasks is a useful practice, remembering those experiences is not just a voluntary act—remembering and forgetting are in fact conditioned and constrained by the contexts of instruction. This paper examines an example as a way to move further a discussion on the role of public memory in mathematics instruction.

In the *Principles and Standards for School Mathematics* (2000), the National Council of Teachers of Mathematics (NCTM) emphasizes the importance of conceptual understanding in mathematics and characterizes it by one’s “...ability to use knowledge flexibly, applying what is learned in one setting appropriately in another” (p. 20). But using that standard to gauge the quality of mathematical work in classrooms might lead to disappointing findings. For it is with astonishingly high frequency that researchers have documented students’ inability to transfer previously acquired mathematical knowledge into new situations (Hiebert & Carpenter, 1992). Why does that happen? We ask that question in the context of examining one case where students failed to recognize the relevance of their existing knowledge of similarity while addressing a new problem. An explanation is proposed that ties students’ recognition and remembering to the context within which mathematical concepts are developed.

### Theoretical Framework

In order to frame an analysis of students’ recognition of relevant previous knowledge, we use Vergnaud’s notion of *conceptual field*. We use that notion to look at both the context of students’ learning of the concepts of similarity, and students’ actions when asked to attempt new problems that involved the concepts of similarity. According to Vergnaud (1996), a conceptual field is comprised of three components –the

set of situations or problems ( $P$ ) that give meaning to the concept; the operational invariants ( $I$ ), or action schemes that put those concepts to work; and the symbols and symbol systems ( $S$ ) used to represent the concept. The latter is meant to encompass linguistic and symbolic tokens as well as other standard inscriptions that might come in the form of figures, diagrams, graphs, or equations.

The recognition that a new problem is related to a previously experienced conceptual field may trigger the implementation of operational invariants from that conceptual field. That recognition may be triggered by the resemblance between new problems and those problems that characterize a conceptual field. Recognition may also be triggered by the presence of the symbols that are characteristic of that conceptual field. Moreover, misrecognition may be explained in terms of lack of perceived resemblance between problems or absence of recognizable symbols. Beyond establishing a means for exploring the understanding of students' perceptions of a particular concept, the use of Vergnaud's theory of conceptual fields allows one to analyze the progress of students during their work with novel tasks using those concepts. Having chosen a problem for students to work on and being aware of some of the experiences which have allowed students to build knowledge of the mathematical concepts involved in that problem, we can hypothesize feasible operational invariants that students might have access to. We can use those to understand what students actually do when they work out unfamiliar problems.

As concepts are encountered and developed through classroom instruction and interaction, one must carefully consider the role of the classroom, specifically the teacher, in the development of conceptual fields. One must remember that knowledge development and use in schools is as much an institutional as a psychological phenomenon. In particular, the way in which public records of past work are generated and accessed often responds to instructional goals and needs. Thus, whereas an observer might consider that a new problem calls for concepts that students have been exposed to, that problem might still fail to elicit students' recognition of those ideas. The implicit regulations of the instructional context in which students have experienced the target concept may help explain such misrecognition (Brousseau, 1997).

### **Methods and Data Sources**

Because of our interest in examining the relationship between instructional context and students' recognition, two kinds of data were collected – classroom observations, and student and teacher interviews. Observations were conducted over a period of three months in a seventh grade mathematics classroom in a suburban, racially and economically diverse school district, taught by an experienced teacher, whom we call Ms. Briar. The classroom used Connected Mathematics, which specifically states as one of its goals to foster in students the ability to transfer mathematical knowledge into new situations (Lappan et al., 1996, 2002), and to use problems as contexts for learning (Lappan et al., 2002). Classroom observations followed the development of the "Stretching and shrinking: Similarity" unit (Lappan et al., 1998). In particular we focused on students' coming to know the theorem that states that the area of a similar

figure “grows by the square of the scale factor” (Lappan et al., 1998, p. 27n), which we refer to as the Similar Figures Area Conjecture (SFAC). Fieldnotes from classroom observations, the textbook, and artifacts from classroom activities serve as sources for describing the context in which the concept of the SFAC was developed in this classroom.

After lessons covering the SFAC were completed, an interview with Ms. Briar was conducted to learn more about how she works to develop students’ knowledge of mathematical concepts. A problem that, from an observer’s perspective might be solved using the SFAC, was used to provide context for a discussion on Ms. Briar’s expectations for her students’ work in a different context. To examine students’ recognition of the relevance of the SFAC in the problem chosen, four students were asked to work on the novel problem in a session led by the first author. Their conversations and reasoning will be examined here.

### **Knowledge of Similarity in the Seventh Grade Classroom**

The conceptual field of the SFAC was developed through a series of investigations in the unit, Stretching and Shrinking (Lappan et al., 1998). The first investigation is designed to introduce the notion of similarity to the students and get them to compare similar figures to discover relationships between them. In Investigation 1, “Enlarging Figures”, students construct a “two-band stretcher” by tying the ends of two identical rubber bands together to serve as a tool for creating similar figures. The stretcher is held down on a point  $P$ , the anchor point, and a pencil is inserted at the other end of the stretcher. Students are instructed to stretch the rubber bands so that the knot tying the two together outlines the picture. Doing this, the pencil traces out a new picture, whose image is twice as large as the original (Lappan et al., 1998, p. 6). The subsequent follow-up questions ask students to compare their “original figure” with their “enlarged image”, in terms of the lengths of the line segments, the angle measures, the general shape, and the area of the two figures (p. 7).

The first author observed the discussion of the resulting comparisons students made between their original figures and the images they had created. Students agreed that the line segments were twice as long, that the angles remained the same, and that the general shapes were retained. What they did not agree upon was the relationship between the areas of the figures. One student asserted that the area of the second figure must be twice as big as the first, reasoning that all of the line segments were twice as long. A second student, whom we call Ryan, contradicted this statement, saying that the image was four times as big as the original figure. His reasoning was that he thought that you could fit four of the original figure into the image. The teacher adopted, “Ryan’s Conjecture” and pursued another example. A simpler shape was chosen and the students were asked to guess how many of the original figure would fit into the enlarged image. Utilizing this new shape, a flag, students could readily see that the image indeed fit four of the original figure. Ms. Briar ended the period by telling her students that they would return to “Ryan’s Conjecture” later in the unit.

The concept of area in similar figures was further developed in Investigation 3, "Patterns of Similar Figures" in the same workbook (Lappan et al., 1998). Students worked with "rep-tiles" during this unit. A *rep-tile* is "a shape whose copies can be put together to make a larger, similar shape" (p. 29). See Figure 1 for an example of a rep-tile, similar to that provided in the student workbook. Students were given several shapes and copies of the shapes with which to construct rep-tiles. The classroom activity deviated from the text here, as Ms. Briar asked her students to construct their own tables to record data about the scale factors of the shapes (two this time, going from original to rep-tile and from rep-tile to original). She also asked them to record two ratios--the ratio of the perimeter of the original to the perimeter of the rep-tile and the ratio of the area of the original to the area of the rep-tile. Here students had a chance to verify that "Ryan's Conjecture" held true and that when objects' perimeters are made twice as large, the area is increased by a factor of four. The teacher pointed out that fact was to the students and the class again referred to the conjecture as "Ryan's Conjecture".

Later in the unit, students constructed another rep-tile that was used explicitly to discover the relationship between scale factor and area. Figure 2 illustrates the problem from the *Stretching and Shrinking* text that students discussed (Lappan et al., 1998, p. 52). Students examined the relationship between scale factor in these three diagrams and created their own diagrams of what the fourth and fifth triangles of this sequence would look like. They discussed the relationship between areas and came to realize that the square of the scale factor told them the factor to multiply the original figure's area by in order to obtain the area of the enlarged image. They did not explicitly write down the formula as a mathematician might (e.g., saying that if the ratio between corresponding sides of similar figures  $a:b$  then the ratio between their areas is  $a^2:b^2$ ). Yet, when determining the ratio of the areas of similar figures, students understood that they could square the scale factor and multiply it by the area. The formula "area \* scale factor \* scale factor" was written on the board and students worked through several examples, calculating areas of figures that were 8 times bigger, 10 times bigger, and so on. Ms. Briar reminded them that this was exactly what Ryan's Conjecture had stated for the case of a scale factor of two.

After developing the conjecture over the course of at least the five days where these three activities took place, students were asked to apply it in various problems. One such application was related to reading maps. Students were given a map of the state of Utah, furnished with a scale, and asked to determine an approximation of the perimeter and area of the state (Lappan et al., 1998, p. 45). In this instance, they could utilize their knowledge of the Similar Figures Area Conjecture and their calculated scale factors from perimeter to determine the area of the state. Another similar application of the conjecture relating measurements considered designing buildings (Lappan et al., 1997, p. 36); the problem's diagram is illustrated in Figure 3. In this problem students were asked to determine the area of the figure on the grid and, using the SFAC, determine the area of the figure if it were built as specified by the scale given (1cm =

40m). It is the context of this problem, successfully completed and explained to the observer by several students, which will closely mirror the problem presented to students during the problem solving session where we had intended to observe students' reasoning and actions as they approached an unfamiliar problem.

*Figure 1.* Rep-tiles. [Redrawn by the authors according to a figure in Lappan, G. et al. (1998, p. 29) ©1998 by Dale Seymour Publications]

*Figure 2.* Building larger rep-tiles to find a pattern. [Redrawn by the authors according to a figure in Lappan, G. et al. (1998, p. 52) ©1998 by Dale Seymour Publications]

*Figure 3.* An Area Application. [Redrawn by the authors according to a figure in Lappan, G. et al. (1998, p. 29) ©1998 by Dale Seymour Publications]

We can use those activities to describe the conceptual field of similarity being developed in Ms. Briar's class, particularly as it relates to conceiving the SFAC. A variety of problem situations (*P*) gave meaning to the SFAC. Specifically, the problem set includes "rubber-band stretcher" problems, "rep-tile" problems, problems involv-

ing reading maps, and problems involving reading architectural plans for buildings. Generically, these problems involved comparisons between the areas of similar figures using the same unit and calculation of the area of a figure, using a given scale factor and the area of a similar figure. However, this problem set by no means exhausts the types of problems that could be created around the SFAC. For instance, students were exposed very minimally to the notion that the SFAC might be used in converting between area measurements of a given figure according to two similar units of measurement, even though the last examples given in class began to touch upon that issue. As we consider the language that came to be associated with similarity, we also note that the conceptual field developed in Ms. Briar's class excluded that kind of problem.

The proposition that we call the SFAC was never actually given a name in the classroom, only informally referred to as "Ryan's Conjecture". But Ryan's Conjecture, which referred specifically to the case where there is a ratio of two between sides and a ratio of four between areas of specific figures, does not fully describe the relationship that students learned during the lessons surrounding this concept. Instead, the relationship is more often signaled for use by the language tokens characteristic of the problems used during its development. Problems of comparison are indicated by the terms "scale factor", "original figure", and "enlarged image" and are seen repeatedly throughout the *Stretching and Shrinking* (Lappan et al., 1998) workbook; furthermore, such terms were heard repeatedly in reference to the need to use the SFAC by the first author during instruction. Indeed, the final version of the procedure associated with the concept of the SFAC was written on the chalkboard as  $\text{area}_{\text{image}} = \text{area}_{\text{original}} * \text{scale factor} * \text{scale factor}$ . In the few problems that required students to transform measures using the SFAC, the problems required "comparison" or "calculation" and the term "scale" was always explicitly provided along with the numerical value to be used as the scale factor.

In addition to the language tokens used to point at the concept, there were representations associated to it. Students might recall the concept in terms of the images of the man they traced with the rubber-band stretcher, the rep-tiles which served as building blocks, or the maps and diagrams that gave them practice in using scale factors in real-life situations. More generally, the images that went along with the concept always included (actually or potentially) two separate figures, distinctly different in size, as source and target of the similarity.

The operational invariants associated with the concept included initially the counting of a given unit inside figures. We saw this first when Ms. Briar drew a flag which students handled by literally counting the number of original figures fitting inside. But even more clearly, we see the method of counting illustrated with the use of the rep-tiles which serve as building blocks for larger and larger figures, and which could easily be counted to determine the ratio between areas of different figures. In problems where they had to calculate an area students would use the formula  $\text{area}_{\text{image}} = \text{area}_{\text{original}} * \text{scale factor} * \text{scale factor}$ . Students began to use the provided scale factor

and an estimate of the area of the “original” figure in order to apply the formula and obtain the necessary measure of area that problems demanded.

### **The New Problem and the Teacher’s Expectations**

The problem chosen to elicit students’ use of the SFAC (borrowed from Stein, 2001) presents an oddly shaped figure, drawn upon a grid where each unit square of the grid is designated as one squared centimeter. Directions indicated for students to determine the area of the figure in squared centimeters and in squared millimeters (see Figure 4). We foresaw this problem as calling for the recognition that the scale factor, in going from millimeters to centimeters, is 10. We foresaw the problem calling for recognition that the two area units involved are similar, that the SFAC helps determine the ratio between the area units, and that this ratio (100) is enough to determine the area of a given figure according to the two units.

Whereas the SFAC might be instrumental for students to solve that problem, there are several aspects of the problem that separate it from those that students encountered in class when they were learning the SFAC. First of all, the problem situation was somewhat new to the students. Although they had encountered grid diagrams asking them to change units in their work with the SFAC, they had not encountered a problem asking them to consider a conversion in squared units. Although the intended action was the same, one might also argue that there was little indication—in the language or the graphical representation—that this was an appropriate action to take. The rep-

Find the area of the shaded region in square centimeters and square millimeters.

= 1 Square Centimeter

*Figure 4.* The problem solving task [Redrawn according to a diagram from Stein, 2001, p. 110; © National Council of Teachers of Mathematics].

resentation of this problem is different from their previous exposures in that not two figures are given or eluded to (an original and an enlarged or reduced one) but just one. Moreover, there is no scale relating  $\text{cm}^2$  and  $\text{mm}^2$  as they had seen in other problems such as the Utah problem. Finally, the language used in this problem is also different than in the problems used to develop the concept. Students are asked to “find the area” instead of “compare” areas; and there is no mention of “scale factor” in the problem.

### **The Teacher’s Instructional Strategies and Expectations for the Problem Chosen**

We were also interested in understanding how Ms. Briar had interpreted and implemented the activities that provided context for the development of the similarity concepts. So, an interview was conducted by the first author, to learn about the different strategies Ms. Briar had used to help students in the problems worked in the classroom. Ms. Briar emphasized the importance of establishing a rich and engaging environment with which to associate the concept so that elements of this environment could be called upon to elicit memories of a particular concept in later instances. Moreover, she emphasized the importance of establishing a diverse language with which to refer to concepts:

One thing is if you’ve got a nice engaging activity, that’s the kids own data, or innately of interest, or that type of thing...so that you can go back to that if you want to stress a point.... We develop an informal language that may make sense only to that class but you keep connecting it and take a more casual approach to the term.... I think the more that comes out of them, the more likely it is to stay.

It seems that such an environment was indeed created around the concept of the SFAC. Problems occurring throughout the development of the SFAC utilized students’ own data and observations while addressing several different real life problem situations primarily through word problems, with settings as described previously. Moreover, as we have seen, Ms. Briar tried to introduce students to a variety of language referents for the concept. The conjecture, first hypothesized by a student, was labeled “Ryan’s Conjecture”. Throughout future development of area comparisons, this label continued until finally formally modified into the equation  $\text{area}_{\text{image}} = \text{area}_{\text{original}} * \text{scale factor} * \text{scale factor}$ .

Ms. Briar also commented on the problem that the first author had chosen to give to students. Interestingly, when asked what she would expect her students to do with the task, she did not foresee that this problem would call for the use of the SFAC. Although she herself described her reasoning through the task using the SFAC, she felt that her students would attack the problem as an instance of conversion of units. This was despite the fact that similar problems, showing transformations across measurement units treated as similar figures, had been presented recently (within two weeks

of the interview and problem solving session) in the text and discussed by students in small groups. Furthermore, she felt strongly that a great number of students would run into problems with converting centimeters squared to millimeters squared, relying instead on their schema of conversion from centimeters to millimeters according to which they would multiply centimeters by 10 to get millimeters. She said about those students who might see the problem as an instance of conversion of units, “what the most common error then would be if they thought...multiply by ten...cause there’s some kids who still don’t know the squared relationship”.

### **Students’ Work on the New Problem**

Four students from Ms. Briar’s third hour mathematics class volunteered to participate in the study. The students, accompanied by the first author, took time away from a normal class period to work together in the school’s library on two problem solving tasks, including the task shown in Figure 4. The group included three Caucasian and one Asian-American student, two males and two females, and covering a broad range of mathematical abilities. Incidentally, one group member was Ryan, of “Ryan’s Conjecture”, the student who had made the initial observation of the SFAC and whose name was associated with the concept throughout the observation period.

The students were asked to work each problem individually for a period of about 5 minutes (when everyone had finished), at which time the group convened to discuss together the work which had been done. All four had correctly answered the first portion of the problem and had utilized the expected method of counting the shaded squares. In order to obtain the answer in squared millimeters, three of the four students utilized what they remembered about conversion of units to multiply their answer in squared centimeters by 10.

Kulp: So, what did everyone get for millimeters squared?

Ryan<sup>1</sup>: 175 millimeters. And I just moved the decimal.

Molly: I got 170.

William: I got 175...

Kulp: ...Okay, so how did you guys go from 17.5 to 175?

Ryan: Well, when anything’s multiplied by 10 you just move the decimal over 1.

Joung was the only student who obtained a different answer to this question – 1700mm<sup>2</sup>. Unfortunately, she could not explain her methods to the rest of the group, insisting only that her answer was incorrect.

It appeared as if the students had recognized the problem as calling for conversion of units and thus implemented operational invariants—moving the decimal point—that were relevant to those type of problems, learned long ago. In doing that, they had

all run into a common error that occurs when converting areas. When asked if there was another way to approach the problem, a way to check their answers, the students remained silent. The students were prompted to consider scale when the interviewer drew in an additional block, this time much smaller and labeled as one squared millimeter. But it was only with the introduction of the particular language associated with the SFAC, in the form of the question “What would my scale factor be to get from here to there (pointing first at the one centimeter squared and then at the added one millimeter squared)?,” that students were able to reconsider their answers. With the label “scale factor” introduced, Ryan immediately changed his original solution to the problem and the others were quick to follow from his explanation.

### **Some Conclusions**

Why is it that the students failed to recognize this problem as an instance of similar figures? There seem to be several characteristics of our problem solving task that are different from those of the context in which students had developed and used the SFAC. First of all, there are key differences between the kind of problem we used and those used around the conceptual field of similarity in the classroom. Notably, the problem did not involve operating on a pair of figures, source and target of a similarity. Furthermore, the symbols involved included tokens that had not been customary in the classroom (squared millimeters and squared centimeters). The problem did not include symbolic cues that would point students to similarity, such as: “scale,” “scale factor,” or “compare” were not included in the problem.

However, one cannot completely alienate the problem from the range treated with similarity. There were certain characteristics of this problem that were (intentionally) similar to previously worked problems, including the problem described previously which used an architectural context to develop an understanding of conversion of units as a unique instance of the SFAC. It is also true that there were concrete differences in the setting of doing mathematics – the students were not in the classroom where they normally use their mathematics, and it was the first author rather than their teacher who was working with them. Yet, we feel that the observed misrecognition owes more to the characteristics of the context (including problem and symbols) than to the difference in settings. At any rate, because a goal of the problem-based teaching embodied in CMP is to foster students’ ability to use mathematical knowledge in new situations that might take place outside of the classroom, we should be interested in examining carefully this misrecognition.

It is significant for this discussion to examine why it is that the actions of the students (treating the problem as a conversion problem and not as a similarity problem) would not have surprised their teacher--as she had forecasted that treatment, as well as the error that students ended up making. One possible explanation, suggested by the second author, is that these students’ actions, which might be thought of as forgetting or as a display of their individual inability to recall and transfer knowledge they have

learned, actually have instructional roots. Those instructional roots become visible when a problem is chosen that breaches the implicit contract (Brousseau, 1997; Herbst & Kilpatrick, 1999) between teacher and students by virtue of which recalling and transfer are made to work efficiently in the classroom.

Students' failure to identify the relevance of the SFAC is actually their success in reading the cues for a conversion problem. In this instance then, we see not an example of the students' forgetting their knowledge of the SFAC, but an example of a problem where the cues at hand are not similar enough to those which have become triggers for the SFAC concept during its development. Thus, the knowledge that students have of the concept cannot be accessed, whether to solve the problem or check the work that they have done on the problem. Only when a cue, associated with the concept, is introduced do students have access to their memory of the SFAC and its related actions. Teacher and students share a mutual understanding, built on the context of instruction that relates how students develop understanding of concepts and how they perceive the relevance of those concepts in problems encountered at a later time. In other words, because instruction must aim at transfer, instructional practices tend to include the identification of central contexts and conditions of transfer. As the potential contexts for transfer are many more than those identified in instruction and some of them might actually be contexts for the teaching of other ideas, it would always be possible to produce a misrecognition like the one observed. But whereas such misrecognition could be considered an interesting effect of instruction we want to stress that we are not suggesting that the particular instruction observed or the particular curriculum being used are to be blamed. Rather, we tend to think that it is a systemic effect that would be more or less observable in any kind of instruction that aims at ensuring transfer.

Certainly, this topic needs to be researched further. An understanding of the characteristics of tasks and the connection between the design of problems, lessons, and units that build multiple ways of organizing and accessing the public memory could have tremendous impact on the work of the teacher and how she negotiates with students the work to be done. And understanding such connections would hopefully allow one to have insights into how to promote the application of student's mathematical knowledge when they are faced with unfamiliar problem solving situations – in the classroom and outside of it.

## THE 'AHA MOMENT': STUDENTS' INSIGHTS INTO THE LEARNING OF MATHEMATICS

Peter Liljedahl  
Simon Fraser University  
pgl@sfu.ca

The moment of illumination – the AHA moment – has long been the basis for lore in mathematics. Unfortunately, these phenomena are reserved almost exclusively for the domain of practicing mathematicians. This study focuses on the impact of these AHA moments on students' affective domain. In particular, I examine the role of the positive emotion that accompanies such moments of illumination in changing the attitudes and beliefs of 'resistant' students. That is, preservice elementary school teachers who deem themselves to be incapable and/or phobic of mathematics and the learning of mathematics but are forced to take an undergraduate mathematics course as qualification to enter into a teacher education program.

At that moment when I put my foot on the step, the idea came to me, without anything in my former thoughts seeming to have paved the way for it...

Poincaré (cited in Hadamard, 1954)

Barnes (2000) calls it the 'magical moment.' Polya (1965/1981) speaks of 'a sudden clarification.' Davis and Hersh (1980) dubbed it 'the flash of insight.' What they are all referring to is the moment in mathematics when an understanding is suddenly achieved. At this moment, what was previously confusing and elusive becomes clear. Learning has occurred, and it seems to have done so in an instant – a moment of learning.

For mathematicians, the 'AHA moment' – as I refer to it – is both an accepted and expected part of the problem solving process. We know that often the solution comes to us; there will be an illumination. And when it comes it is accompanied by feeling of joy and satisfaction. These experiences and the feelings that accompany them, however, are not unique to mathematicians – even within the field of mathematics?

### **Prologue (Motivation and Question)**

Imagine a person who has a dislike for mathematics. Somewhere in their past is a negative experience with the subject – it may have been a single event, or it may have been a series of negative events. The nature of the experience is not clear, but what is clear is the impact that it has had on them as a learner of mathematics. They feel that they "were never good at mathematics", or that they 'can't do mathematics'. Perhaps they are even afraid of the subject, suffering anxiety at the thought of having to endure a mathematics course.

Such a person is not difficult to imagine. We encounter such individuals on a regular basis. They are our neighbor, or brother, our friend – and sometimes they are our student. Now imagine a whole class of such students – 100 plus individuals who, to a

person, would describe themselves as either being incapable of doing mathematics, or having a phobia about the learning of mathematics, or both.

What impact would an experience of illumination have on the individuals in such a group? These are not mathematicians – yet they are working in the field of mathematics. They are not anticipating these moments of insight; they may not even be familiar with such moments. For many of them mathematics has long been a subject devoid of wonder, surprise, and discovery. As a researcher I became interested in what such a population would make of these moments of illumination in the context of mathematics. Where they experiencing them, and if so, what effect were they having on them?

### **Background**

In that moment when the connection is made, in that synaptic spasm of completion when the thought drives through the red fuse, is our keenest pleasure.

Thomas Harris (2000, p. 132)

The learning of mathematics has classically been studied from the perspective of cognition. That is, the examination of what are the cognitive processes involved in learning, and how do they operate. However, the inability of such research to explain the failures of people in problem solving contexts who possess the cognitive resources necessary to succeed has prompted the re-evaluation of the role of the affective domain in the learning of mathematics (Di Martino & Zan, 2001).

The affective domain is most simply described as feelings – the feelings that students have about mathematics. In general it is understood that the affective domain is comprised of beliefs, attitudes, and emotions (McLeod, 1992). The beliefs are just that – what students believe to be true about mathematics (c.f., beliefs that mathematics is ‘difficult’, ‘useless’, or ‘all about memorizing formulas’). Ajzen (1988) defines attitudes as “a disposition to respond favourably or unfavourably to an object, person, institution, or event” (p. 4). Attitudes can be thought of as the responses that students have to their belief structures. That is, attitudes are the manifestations of beliefs (c.f., attitudes such as ‘math sucks’, ‘I can’t do math’, or ‘I was never very good at math’).

Research has shown that both beliefs and attitudes are relatively stable within an individual learner. That is, they change slowly. Thus, changing negative attitudes or misconceived beliefs is a difficult and slow process. On the other hand, stable also implies that such negative feelings are slow to form. Emotions on the other hand, are relatively unstable (Eynde et al., 2001). They are rooted more in the immediacy of a situation or a task and as a result are often fleeting. Students with generally negative outlooks can experience moments of positive emotions about the task at hand and, conversely, students with generally positive outlooks can experience negative emotions.

Because of their stable nature, research has focused primarily on the role of beliefs and attitudes on the learning of mathematics (Eynde, De Corte, & Verschaffel,

2001). The results indicate that attitudes – and as a result, beliefs – are strongly linked to school achievement (Leder, 1992; Ponte, Matos, Guimarães, Cunha Leal, & Canavarro, 1992). Attitudes and beliefs can be viewed as the gatekeepers to learning. That is, before a student can even begin to engage in the learning of mathematical content they have to first decide that they are both willing to learn and capable of learning the presented material. Once that has been decided any residual beliefs and attitudes regarding the learning of the content will continue to affect how they actually learn it. For example a student with the belief that mathematics is about ‘memorizing rules’ will approach new content matter from the perspective of identifying a rule, mastering the use of that rule, and then memorizing that rule – regardless of the intended cognitive outcome of the lesson.

Conversely, the relatively unstable nature of emotions has resulted in little research being done on the impact of this component of the affective domain on the learning of mathematics (for exception see DeBellis & Goldin, 1999, 1993). This is the goal of this study. I am interested in how the positive emotions elicited by an AHA moment affects the beliefs and attitudes of a student and as a result affects their learning of mathematics.

### **Methodology**

Participants in this study are pre-service elementary school teachers enrolled in a ‘Foundations of Mathematics for Teachers’ course that is requisite for entry into a teacher education program. The course runs for the length of one semester (13 weeks) and has four contact hours each week. The data for this article comes from the 112 students enrolled in the course at the time of the study. These students could, for the most part, be described as resistant. That is, they are resistant to the fact that they have to take a mathematics course – as many describe themselves as math-phobic, or at least math-incapable. They do, however, appreciate the fact that they need to learn the course content, as they are highly cognizant of the fact that they need to fulfill this requirement in order to advance into teaching.

The course, itself, is generally regarded as an ‘unpacking’ (or ‘repacking’) course, as it focuses on examining elementary school mathematics from a more general and encompassing perspective. The hope is that such an approach would allow the students to build connections between individual strands of mathematics and facilitate a deeper understanding of the topics as they make sense of all that they see.

At the time of the study I was the teaching assistant for the course. Although the course is taught in a lecture format the students are provided with support in the form of a tutorial lab. The lab is open to students from 20 to 30 hours per week and is manned at all times with between one and four teaching assistants. There are weekly homework assignments and students are expected to work in groups of three to five students to complete these. The group work is not only expected, but also facilitated in the group centred atmosphere of the tutorial lab where the students meet regularly as groups. It was in this lab setting that I had my contact with the students.

The data for this study came from two sources. The first of these is through informal discussions with students as they worked in the lab setting. Students were engaged in a discussion early on in the course regarding experiences of illumination in mathematics. At the time there was no explicit purpose to these interviews other than to use them as a way to enter into a dialogue with the students in an attempt to get to know them. The discussions were very informal and can best be described as conversations.

The result of these initial interviews can be summarized as producing two very prominent trends. The first trend was that students, by enlarge, knew what was meant by an AHA moment – even without definition. Many had alternate names for it referring to it as ‘when it clicks’ or ‘that spark’. Some students assumed I was referring to ‘when you suddenly remember the name of someone or something that was on the tip of your tongue, but you couldn’t remember’. Only a very few students needed me to clarify what I meant by an AHA moment. However, I did provide clarification for everyone, if only to situate the phenomenon, and the discussion, in mathematics.

The second theme that emerged from the informal interviews was how few of the students could recall an AHA moment in the context of mathematics – many of them claiming to never have experienced one. It was this second result that turned out to be the more interesting one from the informal interviews. However, it wasn’t until I began to witness, and hear about, the AHA moments that students were experiencing in working through the course content that I realized that some of these students may be experiencing this phenomena for the first time.

It was this realization that prompted the creation of the second instrument for the expressed purpose of capturing some of these experiences. As part of the course requirements the students were obliged to produce an end of term project. It was decided that one option for this project was to write about an AHA moment they had experienced in the context of mathematics during their participation in the course. This option, as communicated to the students, was prefaced with an anecdote that was meant to describe the type of phenomenon that they were invited to write about.

‘I had been working on the problem for a long time without any progress. Then suddenly I knew the solution, I understood, everything made sense. It seemed like it just CLICKED!’

This was followed by some very specific criteria pertaining to mathematical context, content, and understanding, as well as a conclusion regarding the value of the AHA moment in the teaching and learning of mathematics.

As it was not certain that everyone could claim to have experienced an AHA moment the students were offered an alternative to this assignment. They could, if they wished, engage in a problem-solving task. In order to be fair this option was open to all students regardless of their experience with an AHA moment. The alternate assignment was:

Of the 112 students enrolled in the course, 76 students chose to write about their

On a squared paper draw a rectangle and draw in a diagonal.

How many grid squares are crossed by the diagonal?

In the case of a 3x5 rectangle or a 2x2 rectangle above, we can simply count. However, can we make a decision about a 100 x 167 or a 3600 x 288 rectangle? In general, given  $N \times K$  rectangle, how many grid squares are crossed by its diagonal?

AHA moment. Although the assignment covered a wide range of attributes surrounding their experience (see above) this study focuses on an aspect of the assignment that was not asked for. All but one of the students who chose to write about their AHA moments also felt compelled to relate how the experience made them *feel* – and in many cases, the effect that these feelings had on them. I use the term ‘feelings’ to represent all three of the elements of the affective domain – beliefs, attitudes, and emotions. What follows is a presentation of some of these responses.

### Student's Responses

As already mentioned there were 76 students who chose to write on their AHA moment. Of these, five students misunderstood the instructions and wrote on illuminations that they had experienced in earlier mathematics courses – usually in grades five to 12. However, for the purposes of this study this did not disqualify their responses. As also mentioned, all but one of these 76 students mentioned how they felt when they experienced the AHA moment – even if to only say ‘I felt great’.

However, not all of the students portrayed an accurate understanding of what was meant by an AHA moment. At least one student took the assignment to mean that she was to construct an AHA moment. That is, she came into the lab and sat down at a table and tried to create an understanding of Venn diagrams – a topic that until then had troubled her. In fact, through my tutelage she did manage to construct an understanding of Venn diagrams and then, unbeknownst to me, proceeded to write about this process for her assignment. This would have been fine if there had, indeed, been a moment of illumination within the process – but there wasn't. Instead, there was an

observable slow awakening to the concept. Evidence of thinking of the AHA moment as a slow dawning of understanding was also present in the writing of two other students. Andrea even went so far as to rename the moment the 'AAHA moment'.

Andrea: My AHA moment has come slowly – not all at once, but little by little I am grasping the concept.

The remaining students all presented experiences that were consistent with what was expected in the spirit of the assignment. Although, as already mentioned, everyone expressed their feelings in some capacity what follows is a presentation of some of the more prominent presentations organized according to the themes that emerged from analysing the data. For the purposes of brevity the mathematical context of the AHA moment has been left out.

### **Anxiety**

Although the topic of anxiety was not brought up in the context of the AHA moment 34 students felt it necessary to mention how they felt about mathematics, or about taking a mathematics course as a way to provide a baseline for their discussion on change feelings.

Both Jennifer and Stephanie reflect on how they feel about having to take this course in order to be able to enter into the teaching program. While Jennifer states a dislike for mathematics Stephanie expresses a fear of the subject matter.

Jennifer: I have never been a person that likes or even enjoys math at all, so the idea of having to take this class if I wanted to teach wasn't very appealing to me. So I came into the course with the preconception that it would be just like any other math class that I had taken.

Stephanie: When I entered Math 190, I felt that fear in my stomach return. I needed this course to enter teaching so the pressure was on.

Marcie reflects on her experience in mathematics in general – going all the way back to her negative elementary school experiences.

Marcie: I was feeling emotions that should not have even existed in grade school.

### **Change in Beliefs**

There were 39 students who displayed a change in their beliefs through the experience of the AHA moment. Only a handful of these actually used the term 'belief' in one form or another to express this feeling. Nonetheless, the change in their beliefs comes through in the articulations of their feelings.

Susan expresses how the experience has changed her beliefs on both her ability to solve problems and by which process she uses to produce a solution.

Susan: The AHA moment is inspiring. It makes students believe that they solved that question through reasoning and deep thought, and inspires him or her to seek more of these moments to obtain a sort of confidence and further knowledge.

James reflects on how the absence of these experiences may have contributed to his belief that he was not good at mathematics.

James: For myself, I wish that I'd had more of these moments in my earlier years of high school then I would maybe not have so readily decided that I was not good at math.

The belief of what 'it takes' to be good at math is altered for Lena as she expresses that she now sees that it is not an issue of intelligence.

Lena: Knowing that I could stare at a problem and in time I would understand, gave me more confidence that I could be successful in math. It really is not an intelligence issue.

What is interesting is the variety of beliefs that were affected by experiencing illumination in the context of mathematics. Although most of them centre on students' conceptions of their abilities to do mathematics some students expressed that they no longer see mathematics as being a collection of closed skill tasks that can be solved quickly, as expressed by Kyla.

Kyla: I used to think that if you couldn't get it right away you didn't know how to do it. This is the longest I've ever worked on a problem. I had just about given up when it just came to me.

Although Kyla's response was similar to that of one other student, her response is unique in that she arrived at this conclusion in the context of doing the other option for the final project. Kyla had not intended to write on an AHA moment and so chose to pursue the problem solving option of the assignment. It was during her work on this problem that she had, what she claims to be, her first 'mathematical AHA moment'.

### **Change in Attitude**

Because attitudes are the manifestations of beliefs it was sometimes difficult to discern the two. That is, almost every expression of a change in attitude had a discernable change in beliefs associated with it – and has been counted in the 39 responses discussed above. However, this does not preclude the richness of the attitudes that were changed. Charlotte and Stephen express a change in optimism and expectations, respectively.

Charlotte: I have a better attitude now; I'm more optimistic. This is helpful in learning as complete thought processes can be impeded by a dejected attitude.

Stephen: Also, I enjoy math now. I feel like this success stimulated more success. Now I have raised my expectations in math.

However, there were five student responses that clearly show a change in attitude without a discernable change in beliefs. This is best demonstrated in Kristie's comments.

Kristie: I must admit that math is challenging for me ... after the AHA moment you feel like learning more, because the joy of obtaining the answer is so exhilarating. It almost refreshes one's mind and makes them want to persist and discover more answers. It gave me the inspiration and the determination to do the best that I can do in the subject.

Kristie has most definitely changed her attitude about the pursuit of mathematics in that she is feeling inspired and determined to succeed in the course. What is not clear is whether or not this is as a result of a new belief that she can succeed.

It is clear from the data that the positive emotion that accompanies the experience of the AHA moment has the power to change both beliefs and attitudes. This however does not explain the mechanism by which this is achieved.

### Analysis

Almost all of the participants alluded to a sense of accomplishment that accompanies the AHA moment – most actually using the word 'accomplishment' to describe the feeling. However, it should be noted that although successful completion of a problem is often a by-product of a moment of insight it is not exclusive to this phenomenon. Problem solving is often achieved through the direct application of problem solving tools and strategies available in a student's repertoire of mathematical experiences. This does not mean that they have experienced a moment of illumination. The feeling of accomplishment that accompanies the solution of a problem is most likely associated with one of two things – the production of a solution and/or the achievement of greater understanding. In either case, the phenomenon of an AHA moment can be detached from the feeling of a sense of accomplishment. This is nicely demonstrated in Deanna's statement.

Deanna: After I understood the question and I had completed it, I felt as though I had accomplished something. I felt as though I was somewhat complete in my understanding of the problem.

Having made the distinction between feelings of accomplishments and moments of illumination there is a wealth of research that indicates that repeated success and feelings of accomplishment contribute to a change in attitudes and beliefs. Furthermore, if an AHA moment is one of the phenomena that contribute to a sense of accomplishment then it could be said that accomplishment is one of the intermediaries by

which attitudes and beliefs are changed. Unfortunately, this does not provide a greater description of the mechanism by which the change occurs.

However, there is a clue in what Deanna doesn't state and Elizabeth does that may provide some insight into the mechanism of emotional change.

Elizabeth: AHA moments are those great moments of deeper understanding and clarification of problems where incorrect or incomplete understanding is overcome. These moments inspire us and encourage us to keep going despite the frustration and anxiety that often tends to overwhelm us in times of difficulty when attempting to solve a problem.

Elizabeth articulates very nicely that the AHA moments 'inspire us and encourage us to keep going'. And it is the AHA moments themselves that provide the impetus for this inspiration. This expression of the role of AHA moments was shared by 28 of her classmates.

Are attitudes and beliefs, in fact, stable entities? If they are then it requires successive successes to change negative attitudes and beliefs. The AHA moments provide the inspiration and encouragement to embark on this path of successive positive experiences and in so doing provides an image of feasibility to the student. This would account for changes in both students' attitudes about their abilities to do mathematics and their beliefs about the accessibility of mathematics.

There is another explanation of the mechanism by which changes to attitudes and beliefs are facilitated. Ironically, it is a belief in the potential for change. It could be said that what makes mathematics enjoyable to pursue is the potential of positive emotion – the anticipation of that 'keenest pleasure'. In many ways this is a belief in the potential for change – emotional change. For David, however, the belief in the potential for change is not rooted in the emotions but in the beliefs themselves. His experience with AHA moments provides him with the hope that one day mathematics will make sense.

David: The moment of comprehension is what keeps 'wannabe' mathematicians in the game. The hope that one day, in one instant, the world will mysteriously come into alignment and math will make sense.

### Conclusions

The moment of illumination, the AHA moment, that instance when the connection is made is part of the culture of mathematics. They are the *fishing tales* that mathematicians tell. But they are not the exclusive property of practicing mathematicians. Their power to transform attitudes and beliefs towards the learning of mathematics makes these instances of insight an indispensable resource in the fostering of mathematics students. That they should be taken advantage of is indisputable. The order of business should now be – how to use them? That is, how are we going to orchestrate our students' learning environments to best facilitate the potential for illumination?

# USING PHYSICS AS A TRANSITIONAL TOOL IN THE LEARNING OF CALCULUS

Karen A. Marrongelle  
Portland State University  
marrongelle@pth.pdx.edu

Physical representations of calculus concepts link students' experiences in the physical world with concepts in the calculus classroom. This study describes how students use physics concepts as transitional tools to aid in their understanding of calculus concepts. Transitional tools are objects in the environment or experiences that both separate the learner from another physical object and strengthen his/her understanding of the object using mathematical contexts such as symbols and graphs. The results of this study indicate that when students use physics as transitional tools they use physics in one of four (not necessarily disjoint) ways: Contextualizers, Example-Users, Mis-Users, and Language-Mixers. Each of these categories will be discussed and examples of students in each category will be contrasted.

## Introduction

Physical representations of calculus concepts link students' experiences in the physical world with concepts in the calculus classroom. Many research reports allude to the importance of physical representations in the learning of calculus concepts (Nemirovsky & Noble, 1997; Thompson, 1994), but few specifically address the role of the physical representation in students' understanding of calculus. Many students experience the mathematical concepts of average rate of change, derivative, and integral in physics classes as they study concepts such as motion, force, and electricity.

This paper describes how students use physics concepts as transitional tools to aid in their understanding of average rate of change, derivative, and antiderivative. The focus of this paper is on describing the classification schemes that emerged during my study of students' use of physics as transitional tools in the learning of calculus. The primary research question I investigated was: How do students draw upon physics concepts to inform their understanding of rate of change, derivative, and integral? The setting for the study was an interdisciplinary Calculus/Physics<sup>1</sup> program. I will begin by describing the Calculus/Physics program and my involvement with the program.

## The Calculus/Physics Program

The present study grew out of research done as part of an evaluation of an integrated Calculus/Physics program. The Calculus/Physics program was developed around two overarching mathematical themes: change and superposition. Additionally, the Calculus/Physics curriculum development was informed by recent research in the areas of calculus and physics learning (c.f. Ferrini-Mundy & Graham, 1994; McDermott, 1984) and research in the area of problem solving (Arcavi, Kessel, Miera & Smith, 1998; Schoenfeld, 1985). Each week the students met two days a week with the physics instructor in a laboratory and two days with the mathematics instructor in a

computing laboratory. The final meeting session of the week featured both instructors and emphasized connections between calculus and physics that were salient during the week. A typical class session involved group activities, computer work, experiments, and a short lecture or class discussion. The calculus topics were reordered and coordinated with the physics content. The four basic threads of calculus (function, continuity, derivative, and integral) were discussed first with polynomial functions and then again for other classes of functions (logarithmic/exponential, trigonometric) as they arose in the physics curriculum. This reordering of the calculus topics allowed for a more unified calculus and physics curriculum.

As part of the evaluation of the program, I conducted clinical interviews with students enrolled in the Calculus/Physics course. A preliminary analysis of the clinical interview data revealed that Calculus/Physics students tended to use physics terminology and evoke physics concepts as they solved various calculus tasks. The research conducted during the evaluation of the Calculus/Physics program coupled with a review of the literature led me to further examine students' use of physics as a tool in understanding calculus concepts.

### **Theoretical Framework**

In order to make sense of how students come to conceptualize calculus concepts, it is important to consider both how the students experience the concepts and how the students mentally organize information about the concepts. The idea that symbols represent information is a central theme in mathematics. However close scrutiny of what it means for symbols to 'represent' has led to the examination of the question: *Representation of what, for what purpose?* (Vergnaud, 1987) and more fundamentally, *What does it mean to represent?* The complexity of the task of attempting to answer the above questions can be attributed, in part, to the myriad of meanings of the word 'representation'. In particular, a struggle over the seeming duality created by the colloquial use of the word representation is evident in the literature (c.f. Janvier, 1987).

Nemirovsky and Noble (1997) put forth the notion of transitional tools as part of their emerging psychological perspective that allows for the analysis of an individual's constructive activity by challenging the convention that any given object or picture must reside either inside or outside a person's mind. By rejecting the notion that a visualization must be either internal or external, Nemirovsky and Noble (1997) overcome the common difficulty that arises from the need to describe whether a visual image is internal or external to the student. Transitional tools are objects in the environment or experiences that both separate the learner from another physical object and strengthen his/her understanding of the object using mathematical contexts such as symbols and graphs. For example, a student who talks about the motion of a cart on a track to help him/her conceptualize properties of the derivative is using the cart and track as transitional tools. Note that the cart and track are tools that reside both internally (in the student's memory of the cart's motion on the track) and externally (the physical existence of the cart and track).

### **Methodology**

The present study was conducted at a large, public university in the Northeastern United States. Eight students enrolled in an integrated Calculus/Physics program participated in the study during the 2000-2001 academic year. The eight students in this study consisted of seven male and one female student. The gender balance is reflective of the gender balance in the Calculus/Physics class during the 2000-2001 academic year. This paper will focus on three students, Rob, Terry, and Todd.

### **Data Collection**

The research plan consisted of three main data gathering parts: (1) conducting semi-structured task-based interviews (Goldin, 2000), (2) participant-observation in the Calculus/Physics course, and (3) obtaining copies of students' in-class notes, in-class activities, homework assignments, and examinations. The data was gathered in order to collect information about how the eight students were using physics as they worked through calculus problems. The interview tasks were designed to elicit information about how the students used physics to help them solve calculus problems presented in various contexts. Some of the interview tasks were presented to the students without a physical or other context. For example, students were given a graph of a generic function,  $f(x)$  and asked to sketch the graph of the derivative  $f'(x)$ . The intention behind such problems was to determine if students might talk about a 'generic' problem in a physical or other context. Other interview tasks asked students to find such quantities as average velocity, change in momentum, and gravitational force.

The classroom observations focused on the language used by both the instructor and the Calculus/Physics students. In particular, I was interested in the extent to which the students invoked physics examples and language as they discussed abstract mathematical topics. Finally, the students' work was collected to gather more evidence about how the students were using physics to help them solve calculus problems.

### **Data Analysis**

In the tradition of Stake (1995) who claims that, "There is no particular moment when data analysis begins" (pp. 71), data analysis was an ongoing process throughout this study. The major source of data in this study was the student interviews. The audiotapes of the students' interviews were completely transcribed and checked for accuracy throughout the study. Initial analyses of the interviews were used to inform future interview questions and help focus the classroom observations. Observation notes and notes taken during the clinical interviews were also transcribed.

Three main types of qualitative data analysis were employed in this study: micro-analysis (Strauss & Corbin, 1998), within- and cross-case analyses, and triangulation of data. During the micro-analytic phase of analysis, it was my goal to generate provisional hypotheses concerning students' uses of physics in their conceptualizations of calculus concepts. The result of the microanalysis was the development of a scheme that classified each student according to his/her use of physics. The classifications

are listed in Table 1 with a short description of each. The Language-Mixer category had not emerged at this stage in the data analysis; rather it was during the within-case analysis that the Language-Mixer category surfaced.

The stability of the classifications was tested by means of a detailed within-case analysis of each student. Episodes in the interview transcripts were first coded for evidence of physics use. Then a second layer of analysis was conducted, re-coding the physics episodes according to the Physics Use Classification scheme. During the analyses of the individual students, a new category of physics use emerged: Language-Mixers. This code was developed to account for data that did not fit into any of the other categories. Students were classified as a Contextualizer, Example-User, Language-Mixer, or Non-User based on the Physics Use Classification code that appeared most often. For example, if the majority of episodes for a student were coded as "Contextualizer" then the student was classified as a Contextualizer.

Three independent researchers re-coded selected portions of the data. The independent coders agreed with the original codes 89% of the time for the first layer of coding. The independent coders agreed with the original codes 91% of the time for the second layer of coding.

### Results and Discussion

As a result of the microanalysis, four categories emerged and were refined during the other stages of analysis. The emergent classification categories are Contextualizers, Example-Users, Language-Mixers, and Non-Users (see Table 1).

These classifications refer to the manner in which the students use physics concepts as tools to aid in their conceptualization of calculus concepts. The Physics Use Classifications emerged because I observed marked differences in the way students were using physics as a tool to help them solve calculus problems. The classifications are not hierarchical or necessarily disjoint. Rather the classifications are used as a way to describe student behavior.

The examples that follow serve to highlight differences between the Contextualizer, Language-Mixer, and Example-User categories. The Non-User is not addressed in this discussion since the Non-User does not employ physics as a tool to aid in conceptualizing calculus concepts.

#### Average Rate of Change Tasks

Students were asked to compute the average rate of change between different pairs of  $x$ -values on the graph given in Figure 1. Most students solved the problem by mapping out  $y$ -values that corresponded to the given  $x$ -values and then finding the difference in  $y$ -values and dividing by the difference in  $x$ -values. The students' explanations of this process and their thinking differed substantially.

Rob was classified as a Contextualizer because of his frequent tendency to discuss calculus problems in a physical context. For example, Rob offered the following explanation for his answer to finding the average rate of change between  $x = -1$  and  $x = 2$ .

**Table 1.** Physics Use Classification Scheme

| Physics Use    | Description  |
|----------------|--|
| Contextualizer | Student works and talks through calculus problems as if it were a physics problem. Majority of technical vocabulary used to solve problem is physics terminology. There is evidence that student is thinking about the problem in terms of physics.  |
| Example-User   | Student uses physics examples to justify solutions to problems or to help make sense of part of the problem. Actual problem at hand is solved using mathematical concepts. Student does not submerge the problem in a physics context. Majority of technical vocabulary is mathematical terminology.         |
| Mis-User       | Student's use of physics misconceptions interferes with student's solution to the problem. Student uses physics misconception to incorrectly solve the problem at hand.  |
| Language-Mixer | Student intersperses physics and calculus terminology as he/she solves problem. Student does not immerse problem in physics context or use physics examples to justify solutions or help make sense of problem. Rather, student intermingles physics and mathematical language as he/she solves the problem. |
| Non-User       | Student does not use physics concepts to language to solve calculus problems.  |

One of these axes is distance, the y axis...They use the distance so it [the y-values] would be 4 and 1. And what you basically do is, I think, just like a slope...it would be the change in distance, so  $4 - 1$  would give you 3. And put that over the change in...x. Which would be 2 and 1, so  $2 - 1$ . That would give you 1. So it's 3 over 1.

Although he was presented with unlabeled axes, Rob decided early on that the vertical axis represented distance. Rob's comment, "They use the distance..." indicates that he was reading the problem as if it were a physics problem. Although Rob mentioned slope, it was immediately followed up by an expression about distance. Rob's interpretation of the problem as asking about distance traveled indicates that he was immersing the mathematics in a physical context.

Terry was classified as a Language-Mixer since he typically infused mathematical language and physics terminology as he discussed his solutions to calculus problems.

Figure 1. Students were asked to compute average rates of change between various points on this graph.

Terry's solution to the same average rate of change problem offers a different perspective:

Between  $x_1$  and  $x_2$ , their position, so that's position (1, 1) and at  $x_2$  it's (2, 4). If I remember right, it's rise over run. And so it should be  $4 - 1$  over  $2 - 1$ , which would be 3 over 1. So it would be 3.

Terry's used the word 'position' here to pinpoint the location of the coordinates (1, 1) and (2, 4). Terry's inclusion of ordered pairs in his discussion indicates that he was using the word 'position' to refer to the placement of the ordered pairs in the Cartesian plane, rather than as a distance. Terry used the mathematical 'rise over run' to indicate that the average rate of change is calculated by subtracting the difference of the y-values (rise) and dividing by the difference of the x-values (run).

Todd was classified as an Example-User because he often talked about physics examples to justify his answers. Todd infrequently used physics concepts or examples to help him as he solved a calculus problem. Todd was asked to compute the average rate of change between  $x = 1$  and  $x = 2$  on the graph shown in Figure 1. Todd solved the problem by calculating the difference in y values and dividing by the difference in x values and then added the following commentary when he was asked to discuss how he could justify his answer of 3:

Well, for me that 3 means that it's increased its speed or position – whatever this graph is – by 3. So maybe it's moved 3 spaces forward on a checker-

board or maybe it's a car going 3 miles per hour faster. It's just something that's increased by 3.

Todd used ideas from physics and from his everyday life experiences not to get a handle on his numeric answer. Todd did not use physics concepts or vocabulary to solve the problem; rather he employed physics concepts as a way to make sense of the result of his mathematical procedures.

Rob, Terry, and Todd used physics as tools in different ways as they solved an average rate of change problem. Rob used physics as a way to trigger or motivate the mathematical tasks that he used to solve the problem. Terry used physics as part of his vocabulary and Todd used physics as a means to make sense of his mathematical solution.

### Sketching Derivatives and Antiderivatives

Students were given graphs of functions, derivative functions, and antiderivative functions and asked to sketch related graphs. As observed in the Average Rate of Change tasks, the students' explanations of their solution processes differed significantly.

As I met with Rob throughout the year, I noticed that he, more than any of the other students, tended to talk about most of the problems in terms of physics concepts. For example, Rob was presented with the graph of  $f(x)$  in Figure 2 and asked to sketch a graph of  $f'(x)$ . Rob explained his thoughts on the problem:

...and you'd assume that this is, in terms of physics, this would be position. And you'd be trying to solve what's happening with the velocity. So, position – it seems to be increasing and it's falling, well slowly. Like in terms of  $t$ , it's increasing, it seems to be slowing down and then it turns around and goes backwards.... So I want to show that in my graph.

Figure 2. Students were given this graph of  $f(x)$  and asked to graph the derivative,  $f'(x)$ .

Rob went on to talk about a specific physical situation as he tried to make sense of the graph around its maximum value.

*But to me it seems that - if it was a ball that you pushed across a table and it was a distinct v[elocity]...distance is decreasing and then it stops, turns around, goes backwards. Time is still going.*

Rob also labeled the axes of the graph as distance (y-axis) and time (x-axis) and he also labeled the axes of his solution graph as velocity (y-axis) and time (x-axis). Rob used the axes labels to help him make sense of the physical situation. Rob remembered his experiences describing and analyzing the motion of a ball rolling on a table and used those memories as tools to help him solve this specific calculus task. Rob talked about the problem strictly in terms of velocity and position – a physical representation.

Terry, on the other hand, did not show evidence of using physics concepts as tools to solve a similar problem. Recall that Terry was classified as a Language-Mixer; he often interspersed mathematics and physics vocabulary as he explained his solutions to problems. Terry was asked to sketch the antiderivative of the function in Figure 3. As he 'read' the graph from left to right, Terry said, "*It's got positive slope and it's zero, and it goes to another positive slope. And it goes faster and slower...And over the interval [before the graph crosses the horizontal axis] is increasing and then it is decreasing.*"

Figure 3. Students were asked to sketch the antiderivative of the function shown above.

Terry combined mathematical vocabulary (positive slope, increasing, decreasing) and physics descriptors (faster and slower) as he solved the problem. Terry first talked about the slope of the graph, then using the physical descriptions 'faster and slower' to describe motion, and finished his discussion talking about intervals of the function increasing and decreasing. Terry did not show evidence of using his knowledge of physics concepts to help him solve this problem. Rather, Terry's use of physics was limited to the use of some physics terminology to help him describe the graph. Terry appeared to use mathematical properties of the graph, such as intervals that the func-

tion was increasing and decreasing, to help him solve the problem. Such mathematical vocabulary was absent from Rob's discussion of the problem, indicating that Rob did not depend on the mathematical properties of the graph, but rather the physical properties of the graph, to help him solve the problem.

Todd did not use physics in any way as he solved similar derivative and antiderivative tasks. When presented with the task in Figure 2, Todd first talked about his general method for dealing with such tasks.

So the derivative is basically the slope of a tangent line at a point. So I'm going to take a few points, plot where the tangent line – the numerical value – is, and then do a basic graph from there. So first off I'm going to find the points where the slope equals zero.

Todd did not employ any tools from physics to help him solve the problem or discuss his solution. Rather, Todd used his definition of derivative as a tool to solve this problem. Todd defined the derivative as the slope of the tangent line and he quite literally solved the problem using this definition. Todd's strategy for graphing the derivative was to choose points on the graph of the function, estimate the slope of the tangent lines to those points, and then plot those estimates on a graph of the derivative. Markings on Todd's examinations and homework assignments indicated that he employed this strategy regularly throughout the year.

Rob, Terry, and Todd used physics as a tool in different ways to solve derivative and antiderivative problems. Rob immersed the calculus problem in a physical context and solved the problem based on his memories of experiencing physical phenomena and his understanding of physics concepts. Terry used physics vocabulary as a tool to help him communicate his method of solving the calculus problem. Todd did not appear to use physics in any way to help him make sense of, solve, or communicate his solution to the calculus problem.

### Conclusion

The Physics Use Classification Scheme emerged from the analysis of the data and was developed to describe the major ways in which students use physics as tools to help them understand calculus concepts. Rob, who was classified as a Contextualizer, immersed the calculus problems in a physical context in order to solve them. He used his memories of experiencing physical phenomena as a starting point for which to solve calculus problems. Terry used physics vocabulary as a tool to help him communicate his ideas about calculus concepts. Todd sometimes used physics as a way to make sense of his answers to calculus problems.

Rob, Terry, and Todd relied on their understanding of physics in different ways as they solved calculus problems. Rob, Terry, and Todd each exhibited a different level of commitment to using physics to help him solve calculus problems. The Physics Use Classification Scheme offers an organized way to talk about a student's level of commitment to using physics as a tool for understanding calculus. A natural question arises as to the benefits of being labeled in one category versus another.

Future research should begin to address this sort of question by further examining and comparing the level of calculus understanding of students in each of the Physics Use Classifications.

# VISUALIZING AND UNDERSTANDING VARIATION

Luis Moreno-Armella & Marco Antonio Santillan  
Cinvestav-IPN, CCH-Unam  
lmorenoa@data.net.mx

This work presents an exploration on the mediation role played by the TI-92 calculator. Our interest is located at the concept of variation studied by means of algebraic and, mainly, dynamic representations. In this respect, the idea of visualization plays an instrumental role in the paper. We distinguish two levels of visualization: perceptual and structural, which function as tools to understand the variation phenomena set in a geometric context. We present fragments of a longitudinal study on variation and visualization. The cognitive behavior of the students, when working with the tasks, put forward the transformation of computational tools into conceptual instruments.

## Introduction

We will introduce some results from a longitudinal study on visualization and variation mediated by the TI-92 algebraic calculator. Our experimental results come from questionnaires and interviews with 15-17 olds, in which it was observed that students have deep difficulties when working with the algebraic and the visual representation of variation.

To measure the impact of these computational technologies *as tools for learning*, it is important to identify difficulties students have, when they come to school, and the ones they have when they leave. In our schools, students have their first contact with the idea of variation at about 12-13 years of age. This happens in contexts involving proportional variation using tabular and graphical representations.

## Conceptual Framework

Computing environments provide settings to study the evolving conceptions of students and teachers as they use the tools of the environment. For instance, our students refer to mathematics as a set of symbolic expressions. Accordingly, knowledge of mathematics means being able to use procedures to transform a symbolic expression into another symbolic expression. Graphing tools may produce then, a shift of attention from symbolic expressions to graphic representations.

At first, *mediation* of the calculator has an amplification effect upon the student's cognition. It becomes fundamental to understand the nature of knowledge of students that emerges from their interactions with those mediating tools. This interaction provides additional *expressive power* to her/his ideas and, eventually, an enhanced computing capacity. At occasions, this amplified capacity makes evident for the student her/his conceptual misunderstandings by offering a richer vision of a certain mathematical phenomenon (Berger, 1998). Working with computational tools in school media leads us to face the work from two different angles: as *amplifying* tools and as *cognitive reconceptualizing* tools. These amplification and reconceptualization processes can be illustrated in the following way: The amplification process is similar to

the function of a magnifying glass. Through this lens, we can enlarge objects visible at first sight. Magnification does not change the structure of the objects that are being observed, however, on the other hand, the reorganization process can be compared to the act of seeing through a microscope. The microscope allows us to observe what is not visible at first sight and, therefore, to enter a new plane of reality. In this way, the possibility of studying something new and of accessing new knowledge arises.

We distinguish between *to see* as “recognizing the content in a graphical representation” (this concerns *amplification*) and *to see* understood as “recognizing structural relationships in a graphical representation” (this concerns *re-conceptualizing*). The latter meaning is what we call *to visualize*.

*Perceptual variation* is linked with physical operations and *representational variation* is linked with symbolic operations.

In our experimental work, the calculator played the role of a probe to explore students’ cognition. The calculator allowed us to (partially) penetrate into the students’ mind looking for information on their mathematical thinking.

## Experimental Results

### Experience One

At the beginning, we designed five questionnaires trying to identify the notion of variation by means of algebraic and graphical expressions. The questionnaires were applied to a population of about 400 students (15-17 olds). Just to give a flavor of this work, let us introduce a questionnaire designed to explore variable magnitudes using algebraic expressions.

Two students, Maria (M) and Juan (J) go to school. Maria walks in such a way that her distance from school can be represented by  $M(t) = t^2 - 4t + 4$  (she begins walking from home); Juan’s distance from school can be represented by  $J(t) = 3t + 4$  (walking from home too). The variable  $t$  obviously denotes time (in minutes).

The following questions were asked:

- 1) What is Juan’s (or Maria’s) distance from school when he begins walking?
- 2) Is there an instant when Juan’s distance from home is 6 meters? In that case what how long is the time spent?

From the first level (15 olds), 99 % of the students were unable to answer correctly any of the questions. 77 % of the students from the third level (17 olds) gave partial correct answers or could answer correctly one of the questions. A general conclusion that can be extracted from this work, is that students have serious difficulties dealing with algebraic models. They find it hard to give meaning to this kind of representations.

### Experience Two

In this section, we introduce a (videotaped) task aimed at examining the mediating role (Chassapis, 1999) of the calculator in the expression of knowledge that

students constructed during geometric activities. We were probing the cognitive activity of students, to try to discover ways in which object manipulation help students understand the invariant properties of a geometric object. This is a key task when researching variation.

We suggest that the students' expressions of coherent and meaningful mathematical propositions prove that they have constructed the relevant relationships or, in other words, the structural links that constitute a figure (Moreno & Block, 2002).

Looking at Figure 1, the teacher asks the students to do the following:

Teacher: Drag point B to the right and then to the left along the arc, but look carefully and try to answer these questions:

- 1) Does angle B change when you move point B along the arc?  
Take point A and drag it to the left and to the right. Does angle B change?
- 2) Take point C and drag it to the left and to the right. Does angle B change?

Figure 1

Before the students started to complete the task, the instructor questioned them about their previous knowledge on the subject. Only one student knew that the angle B, in Figure 1, remains constant as long as one does not move points A or C. Interestingly, the students did not know how to explain this behavior. None of the participants had met the central angle theorem or that a triangle inscribed in a semicircle is always right. The following are some of the participants' answers taken from the task sessions:

Felipe: It looks as if the angle doesn't change even though point B is moving!

Manuel: Let me see, I can't see... maybe...

Felipe and Manuel are talking about Figure 1, while dragging point B to the left and to the right in their calculator screen.

Teacher: Do you think that the angle will change?

They both answered yes, and this is exactly what the rest of the group was expecting.

Teacher: (addressing the entire group) Observe what is changing and what is not changing, and try to keep on doing the task. If you find something interesting for you don't hesitate to tell me.

The participants worked for 20 minutes on this task. Then the teacher proposed the following construction and asked the corresponding questions:

Draw the segments from A and C to the center O of the circle (in Figure 1). Drag point A to the left and to the right; observe angle B as well as the angle formed by the segments that connect points A and C to the center O of the circle (central angle). Repeat the operation with point C.

Move point A or point C until they are collinear with O, the center of the circle. How is angle B changed?

Felipe and Manuel, moved point A until it was collinear with point C and with point O. Finally, they moved point B, showing the teacher what they were doing at every moment. The rest of the participants observed what Felipe and Manuel had found.

Felipe: It looks like when the angle in the middle is  $180^\circ$ , angle B is  $90^\circ$ !

Teacher: Why are you saying so?

Manuel: We have already tried it, and it seems that way. Look!

After 20 more minutes, nobody could further expand the argument about the rightness of the angle B. Then the teacher proposed the students to measure and label the central angle and angle B. After 15 minutes, the students called the teacher and showed him a table in a notebook, one column showing the values for angle B and the other showing the values for the central angle.

Felipe: One column is almost twice as large as the other!

Teacher: How can you express what you found?

Felipe: The center angle is two times greater than the other.

Teacher: Just like that?

Felipe: Ah ... Within a circle the center angle is two times greater than the other.

The aim of these teaching sessions is to study how students express their arguments from the exploration of the different elements in the figures provided. Of course, exploration and expression are possible, in enhanced ways, because of the *executable* representations provided by the software (Cabri-Geometry, in this case). The central

angle theorem is a conceptual tool to link circles, rays, radii and tangents, to create a *local organization* (Moreno, 1996) from a fragment of geometric knowledge.

### Experience Three

Let us discuss another (videotaped) task posed to students from third level (17 olds).

Given a circle with center  $O$  and radii  $OA$  and  $OB$ .

Figure 2

Consider the triangle  $OAB$ . Keeping  $O$  and  $A$  fixed, move  $B$  on the circle. The instructor asks if moving  $B$  changes the area of triangle  $OAB$ . Jacobo's and Luis' answer (before seeing the dynamic process made feasible by the calculator) is: "The area is changing." Afterwards, they arrive at the conclusion that the largest area is obtained when "the triangle seems to be right." The instructor asked *what* were they looking at: "Inside the triangle" was the answer. Let us notice that this activity is far from trivial.

When the students *observed* that point  $B$  moves slowly on the circle Luis modified his first answer. Then he said: "the area remains the same." Jacobo did not agree with this new answer, but could not give an argument against it.

The instructor, trying to mobilize their ideas, asked if the triangle's perimeter was changing. Luis answered: "If the perimeter changes, then the area changes." Luis and Jacobo agreed: "the area is changing and the largest triangle must be right" sustaining this statement in that the change of area depends on the central angle. Luis said: The greater the angle  $AOB$ , the lesser the area.

The next moment, the instructor (I) asked:

Instructor: What happens to the area when the central angle  $AOB$  diminishes?

Luis: It gets larger

Instructor: But eventually the area gets smaller...

Luis: No.

These fragments of the dialogue shows that the students' perception (*to see*, first definition) is fairly correct, but when they have to produce an argument (trying to reach the level of *visualization*) their reasoning becomes confusing. Dragging the figures (or an element of a figure) on the screen generates a sequence of figures in real time. Manipulating this sequence discloses for the student a "mathematical behavior" of the figure that is tangible from the perception level. The student has the opportunity to integrate this behavior into a general image, a kind of general or generic picture. This lets the student to access to the visualization level, that is, recognizing structural relationships in a graphical representation. From the dialogue above we can appreciate that the students answers vary as they explore the figure with the help of the dragging capability of the dynamic geometry software. Even if their answers do not show a full understanding of the mathematics involved, they were able to overcome the plain perceptual level (reading the figure at a superficial level). They found a key structural

Figure 3

Figure 4

relationship hidden (to them) in the figure: The role of the central angle, as illustrated by the following two figures.

When the point B moves to the right, then the central angle at  $o$  increases. Increasing the angle changes the area of triangle  $AOB$ . What is specific of a drawing is incorporated into a generic image. Thus, visualizing is a generalization process.

Articulating the sequence of figures into a whole, makes feasible a new reading of the figures involved. The student can see changes in the sequence (the area, for instance) that belongs to the sequence, that is, to the generic image. This technology provides a new representational infrastructure with high potential for geometry teaching and learning.

Using technology should provide students richer representational infrastructures and their corresponding processing. This should open a window of opportunities to explore mathematical situations posed to them.

### Final Remarks

The use of calculators, in particular, algebraic calculators, is important to promote a mathematical way of thinking that is consistent with the practice of the discipline.

Electronic technologies –calculators and computers- are essential tools for teaching, learning, and doing mathematics. They furnish visual images of mathematical ideas, facilitate organizing and analyzing data, and compute efficiently and accurately. They can support investigation by students in every area of mathematics.... When technological tools are available, students can focus on decision-making, reflection, reasoning, and problem solving. (NCTM, 2000, p.24)

When students make use of technology in their learning experiences, it becomes important to document methods and strategies that appear as fundamental in their mathematical thinking. We should be able, eventually, to answer questions that include:

**What kind of mathematical thinking can be enhanced with the use of technology while learning the discipline?**

Students' growing familiarization with computational tools allows these tools to be transformed into mathematical *instruments* in the sense that computational resources are gradually incorporated into the student's activity. We suggest then, that exploring with computational tools eventually allows students to realize how the mediational role of these tools helps them to re-organize their problem-solving strategies (Guin, D. & Trouche, L. 1999). Working with the virtual versions of mathematical objects provided by the algebraic calculator, promotes the constructive activity of students. Indeed, these virtual versions produce the sensation of material existence, given the possibility of changing them where they exist, that is, on the screen. We suggest, then,

that exploring with computational tools eventually allows students to realize how the mediation role of these tools helps them reorganize their problem-solving strategies. In the absence of these, it is almost not feasible for students to establish a conjecture, nor are they capable of producing a formulation associated with their explorations and express it in the language of the computational medium in which they are working. The computing environment is an *abstraction domain* (Noss & Hoyles, 1996), which can be understood as a scenario in which students can make it possible for their informal ideas to begin coordinating with their more formalized ideas on a subject.

# **SEEING U.S. REFORM TEACHING IN A JAPANESE CLASSROOM: MUTUAL ADAPTATIONS IN FIRST GRADERS' LEARNING TENS ADDITIONS**

Aki Murata  
Northwestern University  
amurata@northwestern.edu

Karen C. Fuson  
Northwestern University  
fuson@northwestern.edu

In order for a mathematics classroom to be truly effective, allowing students to invent their own methods is not enough. Students can also be supported to learn more effective methods while their understanding is developed further. Using a Japanese Grade 1 classroom as an example, we illustrate how students' ideas are valued, how reflection and analysis of different methods deepen student understanding when connections are made among different methods, and how students gradually develop ownership of the culturally-valued method in a sense-making environment. The study found that through the three phases in the unit of addition with totals in the tens, students shifted from using various methods based on their prior knowledge of embedded numbers to making tens to add numbers.

## **Perspectives**

The recent U.S. reform movements propose a new vision of mathematics classrooms where individual students' ideas, interests, and experiences are valued while classrooms as a community develop their understanding of mathematics together (National Council of Teachers of Mathematics, 1999). This sometimes gives a false image to teachers that while students are inventing their own strategies and constructing understandings, teachers should not teach at all (Fuson, in-press). This perceived dichotomy confuses not only teachers about the potential effectiveness of instruction but also students about the expectations they should have for their learning. We propose that in order to establish a truly effective classroom environment, we need both --- student-generated ideas and good teaching. When students' ideas are valued and connected to culturally-valued ideas through classroom activities in a sense-making environment, we are teaching for understanding.

The Vygotskian view of learning focuses on the ways in which the child's spontaneous informal knowledge is bridged to formal knowledge that is valued in the community through interactions with a more-experienced partner (Vygotsky, 1978). The ideas exchanged between the child and the partner are gradually internalized by the child while he/she moves along his/her learning path, and the mutual engagement of the child and the partner creates the necessary support for the learning. This is not a passive process in which the child "receives" new knowledge, but rather is an interactive process in which both partners continuously assess and change the patterns of their interaction to make progress toward the goal. Rogoff (1990) calls this "interdependent goal-directed activity" where both partners work together to reach a certain

goal. Through guided participation in the inter-dependent and goal-directed activity, a shift occurs where the ownership of the activity is gradually transferred from the partner to the child, and the child increasingly becomes a more active agent in his/her own learning.

In a classroom setting, multiple learners are making their negotiations simultaneously as they engage themselves in learning activities. Cobb and Yackel (1996) illustrate the “global shift in classroom mathematical practices” using the example of a group of second graders learning the base-ten system. While students shared individual solutions to the problems, the classroom as a community developed a taken-as-shared method, and individual students’ engagement in mathematical activities with their teacher and peers generated the support for their learning. Thus, students actively contributed to the evolution of classroom mathematical practices as they reorganized their individual mathematical thinking, and at the same time, their participation in the activities provided opportunities and limitations in such cognitive reorganizations.

This study attempts to extend our existing knowledge of effective classroom teaching by examining the ways in which students’ ideas and a classroom-taught method are connected, negotiated, and understood through classroom activities in a Japanese mathematics classroom. Japanese classrooms present many characteristics of U.S. reforms, and examining how learning takes place in an effective Japanese classroom may help us understand how learning takes place in mutually adaptive ways.

### **Methods**

Twenty-five (25) Grade 1 students and their classroom teacher Mr. Otani participated in the study (the real name of the teacher is used because of his request; all student names are pseudonyms). The study was conducted at a full-day Japanese School in a suburb of a midwestern metropolitan city. The school is operated by the Japanese Ministry of Education and closely follows the Japanese National Course of Study. Administrators and teachers are sent directly from Japan through the ministry, and the instructional language is Japanese. The school houses approximately 200 students in 1<sup>st</sup> through 9<sup>th</sup> grades. These students typically come to the U. S. due to their fathers’ work in the metropolitan area. The families who relocate under these circumstances typically stay in the United States for 2 to 5 years and go back to Japan afterwards. They are different from other ethnic minority groups in the United States who immigrate to stay. This Japanese community puts much effort into preserving the culture in their children’s lives because they wish their children to have successful experiences when they go back to Japan. For that reason, maintaining Japanese ways of teaching and learning is considered to be important for the community.

Observation fieldnotes, videotapes, notes from interviews with Mr. Otani, and classroom artifacts (copies of worksheets, tests, quizzes, etc.) are the data sources for this study. The unit focusing on addition with totals in the teens was chosen to be the focus of the study because the focus of the unit—learning of the break-apart-to-

make-ten (BAMT) method—is considered culturally important because it provides a foundation for students’ learning of multi-digit addition and place value understanding in the future (e.g., for  $9 + 4$ , take 1 from 4 and add to 9, add 10 and the 3 remaining in the 4 to make 13). The unit consisted of 11 lessons over a three-week period. The classroom was observed daily during these lessons.

While the classroom was observed, careful fieldnotes were taken to record (1) the general lesson procedures, (2) teaching-learning activities and their structures, (3) kinds of student participation in the activities, (4) students’ engagement and reaction to the activities, (5) verbatim whole-class and small-group discussions (as many as possible of the latter), (6) questions and responses of Mr. Otani and of students, and (7) conversations among researcher, Mr. Otani, and students before, during, and after the class. The lessons were also videotaped to support and supplement the observation fieldnotes for the analysis of the foci stated above.

Data from the observation fieldnotes were analyzed to illustrate (1) how different student ideas emerged in the course of the instruction, (2) how the taken-as-shared classroom mathematical method was negotiated and developed in the classroom, and (3) how individual methods and classroom practices enabled and constrained each other as they guided students’ learning.

In order to identify the changes in the methods used in the classroom, fieldnotes were coded for the problem-solving steps students took in the whole-class context and individually in independent work as they learned to use the BAMT method for addition. Representational drawings, teacher’s questions, and finger use that supported the learning were also identified. Special attention was paid to the methods students used, difficulties students had, and the adjustments Mr. Otani made to support students with these difficulties. Table 1 presents the steps (1), (2), (3), and (4) students took to solve addition problems using the BAMT method and the visual representational support in the textbook and used on the board by Mr. Otani. Fieldnotes were coded using the steps (1), (2), (3), (4) to illustrate general changes in students’ use of the method in the classroom.

## **Results and Discussion**

As with U.S. lessons, mathematics lessons taught in Japanese schools vary in terms of their structure and/or purpose. Some lessons are open-ended in nature, and students are encouraged to explore and investigate a significant mathematical problem on their own. Other lessons are more focused on skill building. Although the Japanese lessons that attracted U.S. attentions in the Third International Mathematics and Science Study (TIMSS) were largely open-ended and investigative (TIMSS, 1997), Stevenson and Stigler (1992) also reported that some Japanese lessons they had observed were mainly of repetitive practice and seatwork.

The present study found similar variation among lessons within the unit and that these different types of lessons worked together to support different phases of student

**Table 1.** The Break-Apart-To-Make-Ten (BAMT) Method (Example:  $9 + 4$ )

| Steps | Description of steps                   | Visual representational drawings   |
|-------|--|--|
| 1     | Realize that 9 needs 1 more to make 10 | $9 + 4$  |
| 2     | Separate 4 into 1 and 3                | $  \begin{array}{c}  9 + 4 \\  \swarrow \searrow \\  1 \quad 3  \end{array}  $       |
| 3     | Add 9 and 1 to make 10                 |   |
| 4     | Add 10 and 3 to make 13                |  |

learning. There were roughly three phases within the 11-lesson unit as students learned to add numbers with totals in the teens. The unit started with an open-ended question and student sharing of ideas, shifted to developing understandings of and skill with the BAMT method, and then focused on gaining fluency with the method. The shift was gradual and was supported by Mr. Otani through questions and continued sharing of different ideas. Students maintained the ownership of their learning through the unit. The balance between exploration of various methods and practicing a certain method appeared to be important in the classroom as student learning was guided to bridge from their spontaneous ideas to a more culturally-valued method.

For the first phase (lessons 1 and 2), classroom time was spent largely for sharing of different ideas of students. Students as well as Mr. Otani worked to understand what they had brought to the classroom learning setting. For the second phase (lessons 2 and 4), students worked to apply various student-generated methods to different addition situations to deepen their understanding of those methods guided by questions by Mr. Otani. Students reflected and analyzed the methods across different numbers. As they

increasingly become aware of the benefit of using the BAMT method, they voted on that as the classroom method to be used. For the final third phase (lessons 4 to 11), students spent time gaining fluency with the BAMT method. This not only provided opportunities to develop skills but also strengthened understanding by students of each of the steps in the method. Students gradually gained ownership of the method as their own. The discussion of each phase follows.

### **Phase One: Sharing of Student Methods**

From the very beginning of the first lesson, students' ideas and contributions drove the lessons to a considerable extent. All the contributions were recognized and appreciated by Mr. Otani and peers, and students actively shared and discussed different methods and ideas. Although Mr. Otani was the one who guided and assisted student discussions for a productive interaction, it was also very clear that students were important mathematical contributors and thinkers in the classroom.

For the initial introduction of the unit, Mr. Otani showed a group of 9 blue magnetic counters and a group of 4 red magnetic counters side by side on the blackboard. Some students immediately shouted out the answer "13!" Mr. Otani then initiated discussion by saying, "Some of you are quick in telling the answer, but who can share with the class your thinking?"

Several students raised hands to share their ideas. Sakiko went up to the board when called and moved one red counter to add to the blue group.

Sakiko: From 4, I add 1 to 9 and make 10.

Mr. O: So, the 9 became 10 and 4 became 3?

Sakiko: Then we know 10 and 3 make 13. We learned that before.

Mr. Otani summarized Sakiko's method on the board and continued to ask for other students' contributions to drive the discussion.

Mr. O: Anyone did this differently?  $9 + 4$ ? Nobuhiko?

Nobuhiko:  $9 + 4$  is ... at first, 3 and 4 is 7.

Students: What? What are you saying? We don't understand! (Overlapping comments)

Mr. O: Will you say it again, Nobuhiko?

Nobuhiko: Took 3 from 9 ... (moves 3 counters from 9).

Mr. O: Took 3 from 9?

Nobuhiko: Add that 3 and 4 ... (put 3 and 4 counters together)

Mr. O: So, 9 is ...

Nobuhiko: 9 became 6. Separate 9 into 3 and 6.

Mr. O: OK.

Students: Oh, that's what he meant. I know it now. (Overlapping comments).

Nobuhiko: Then, 7 ... I mean ...

Mr. O: 7?

Nobuhiko: Became 7. 4 and 3 became 7, so 7 and 6 is 13 (points to the counters)

Mr. O: 13. 7 and 6 make 13. You like  $7 + 6$ , don't you?

Students: Nobuhiko has remembered those partners for a long time!

Mr. O: Is that so? (Friendly laughter)

Students: Yeah, he always does this way. This is Nobuhiko's secret method!

Students worked to understand and evaluate Nobuhiko's solution method as he made a contribution to the discussion. His seemingly incomprehensible idea at the beginning (" $9 + 4$  is ... at first 3 and 4 is 7") was gradually clarified by guiding questions from Mr. Otani. As other students accepted his method as a valid mathematical approach, their ideas become connected. While Nobuhiko worked to articulate his idea to communicate with his classmates, he took time to explain one step at a time, and careful reflection on his own thinking helped develop mutual understanding in the community. Other students also actively evaluated the quality of Nobuhiko's explanation by demanding that he describe the process of his thinking with clarity, and by doing this, individual students in the classroom and Mr. Otani negotiated and tried to establish the shared criteria for what a good mathematical solution and explanations of such a solution should be.

Koichi then shared his method as he changed the addition situation into  $5 + 5 + 3$ . Tadashi volunteered to show the class how he counted unitarily, from 1 to 13 to get the answer. Following his contribution, two students shared different counting methods: Tetsuhiro counted by 2s, and Tomoko counted by 3s. Although counting was not the official topic of the lesson, Mr. Otani allowed students time to explain, and he then summarized to the whole class how counting by 1s, 2s, and 3s were different from one another.

Mr. Otani then summarized the different approaches shared by students at this point. The break-apart-to-make-ten (BAMT) method was called the "Sakiko method," changing into  $7 + 6$  was called "Nobuhiko method,"  $5 + 5 + 3$  was called "Koichi method," and the different counting methods and other recomposition methods that used different break-apart pairs of addends were also named after the students who shared those particular methods. The Sakiko method (BAMT) was the primary method to be taught in this unit according to the curriculum, but Mr. Otani spent approximately equal amounts of time explaining each method at this point by asking students questions.

Thus, at this beginning of the unit, Mr. Otani welcomed students' different ideas and allowed room for diverse methods. The sharing process was important at the beginning of the unit because it provided opportunities for students to review previously learned concepts, demonstrate their competence, and set the stage for future exploration. Student discussion was carefully directed by Mr. Otani to focus around the process of solving the problem, and that provided opportunities both for the students who already knew the answers and for those who were experiencing such large problems for the first time. The students' sharing of methods was the driving force of the discussion, and they spent time developing clear explanations to show their thinking with the visual representational supports on the board.

### **Phase Two: Applying Student-Generated Methods for Different Numbers and Developing Understanding of the BAMT Method**

Next, Mr. Otani extended students' understanding by using the new addition situation of " $8 + 5$ " (this problem requires a partner of 2 to make 10 with 8). He asked students to apply the methods they had come up with as a class to solve the new problem.

Mr. O: Who can explain again how to solve this ( $8 + 5$ ) using the Sakiko method?

Sanshiro: We can separate 5 into 2 and 3, and make 10 with 8 and 2, then add 3 to make 13.

Mr. Otani summarized Sanshiro's explanation on the board using the counters and the visual representative drawings (see Table 1) while verbally reviewing the steps by asking students. Mr. Otani then continued to focus on giving careful descriptions for different methods using different representations (numbers, drawings, counters, etc.) as students shared their methods. Students were given opportunities to deeply think about, analyze, recognize, and discuss these methods.

Mr. O: Will anyone explain other methods?

Yutaro: Nobuhiko method was different. He moved 2 blue (counters) and added to 5 (red counters) and made 7 and 6.

Mr. O: (Moves counters as Yutaro suggested,) so we had 7 and 6. Any other way?

Koichi: Move 3 blue ones aside to make groups of 5, 5, and 3.

After Mr. Otani demonstrated the Koichi method with counters, he drew representations for each of the methods side by side on the board for comparison.

Koichi: Any way we did, we got 13!

Students: (Overlapping comments, they agree all the answers were 13.)

Mr. O: I see how  $7 + 6$  is 13, and  $5 + 5 + 3$  is 13, too. But I want you to look at Sakiko's method here. Why do you think she made 10?

Akemi: ... (Quietly,) maybe because we learned that before?

Mr. O: Let's listen to Akemi now. Will you say that louder?

Akemi: Because we learned that 10 and 3 is 13 in the first trimester.

Mr. O: So, Sakiko method may be the easiest because we have learned this before. Did we learn  $7 + 6$  before, too?

Students: (Overlapping comments) We did! We didn't!

Mr. O: I don't think we learned  $7 + 6$  in the classroom. So, I think making 10 may seem like the easiest method to us now because of what we know already.

By applying the BAMT method in different situations ( $9 + 4$  and  $8 + 5$ ) while also making reference to other students' methods, the connections between the BAMT method and the ideas students brought with them were strengthened and their understanding of the BAMT method as well as the addition situation grew. Subtle but important negotiations occurred in their math discussions as they worked to find the "easiest" method to be used in the addition situations. When students voted for the method they thought the easiest to use in this addition situation, the Sakiko method of making ten received the most votes, and all other methods also got several votes.

Students also took time to think about and continued to discuss the reason why the BAMT would be the easiest method. Guided by Mr. Otani's questions, they explored the base-ten number structure and the importance of "tens" in our number system. Mr. Otani wrote the numbers 0 to 19 on the board in two rows (0 to 9, 10 to 19, with the teen numbers under the 0 to 9) and asked students if they noticed any pattern.

Mr. O: This may be something you had known even before you started first grade. Let's read this together (he points to the numerals as students read them).

Students: 0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19.

Mr. O: Does anyone see a pattern?

Hiroshi: ... 10 is 1 and 0, 11 is 1 and 1.

Mr. O: What do you mean, Hiroshi?

Hiroshi: 10 is under 0 and is (written as) 1 and 0. 11 is under 1 and is (written as) 1 and 1.

Mr. O: Is everyone OK with this? It seems like Hiroshi noticed the way we write numbers?

Makiko: ... We only use 9 numbers to write numbers, like 1, 2, 3, 4, 5, 6, 7, 8, 9, like that.

Students" (Overlapping comments) What is she saying? We don't understand!

Mr. O: ... I think what Makiko is saying is that we use those same numbers repeatedly to write different numbers. Let's see how we do this. 1, 2, 3 ... (point to numbers on the top row, 0 to 9, as students read along).

Students: 1, 2, 3, 4, 5, 6, 7, 8, 9 ... 10? (Seeing the numeral 9) 9? 10? (Discussion among themselves, some students seem confused)

Mr. O: Look up here. OK? We may take this for granted, but we have 10 numerals, 10 numbers, and all the numbers are written with these 10 numbers. So, ... after 9, the next number is ...

Students: 10!

Mr. O: 10, because after 9, we don't have a new number. And, we think 10 as a chunk, and put that chunk in the tens place ... so making 10 as we add numbers make senses here.

The students actively made sense of the addition situations throughout the phases one and two. Mr. Otani valued diverse thinking of students by asking them to share different methods, maintained ownership of ideas by referring to the methods using the students' names, and encouraged critical thinking by having different students explain and apply the method in a new addition situation. Although voting in this initial lesson divided students into different camps, this voting for "the easiest method" continued on to subsequent lessons until on Day 4 all students agreed that BAMT method is the most useful method in the addition situation. This helped individual students to express their choices, and with Mr. Otani's gentle guidance concerning the generality of this method, students gradually made their own decisions for their learning as they came to experience the generality and effectiveness of the BAMT method and recognized the value of this culturally-important method.

### **Phase Three: Gaining Fluency With the Method**

After the third lesson of the unit, the classroom learning focused increasingly upon the practice to gain fluency with the BAMT method. The general steps that are involved in solving an addition problem using the BAMT method are summarized in Table 1. The steps (1), (2), (3), and (4) specify the process students took to solve the problem using the method. Mr. Otani's questions for the whole class or for individuals elicited descriptions of steps of the methods and not just answers. Representational drawings accompanied the teacher's questions to help students visualize the steps they took to solve the problem.

The whole-class practice was the essential learning experience for the students. During it, Mr. Otani varied his levels of support to meet the learning needs of the whole-class and of individual students effectively. This whole-class practice was sometimes done as all the students shouted out answers together to Mr. Otani's question, or at other times individually as students responded to Mr. Otani's question while the whole-class supported the individual students by shouting out the whole-class feedback of "It is OK," or "It is not OK."

This shifting between whole-class and individuals-in-whole-class practice was done in a way to effectively support individual students' learning and engagement. As the classroom community worked to solve addition situations with 9s first ( $9 + n$ ) and then moved on to 8s ( $8 + n$ ), and 7s and 6s, Mr. Otani first used the whole-class practice where all students were encouraged to energetically call out answers together. In these activities, Mr. Otani typically had several problems written on the board, and as he pointed to one problem at a time, students energetically said answers together to the question about the steps of the method. Mr. Otani then moved to ask individual students the same questions as an extension of the previous whole-class exercise, while students who were not answering supported the responding student by giving the oral "OK" feedback. At the final stage, students worked independently or as pairs in their notebooks to solve problems. Mr. Otani varied this pattern sometimes. When he felt that students were not engaged enough in individual practice, he then switched to whole-class practice so that all students could participate together.

While the whole-class practice helped the students move forward as a group, the teacher individuated support when students gave answers individually. While the class engaged in individual practice in the whole-class context, Mr. Otani varied his support to meet individual student's needs.

The purpose of this last phase of the unit when lessons focused on practice of the BAMT method was not merely drilling for skill. It provided important learning opportunities and helped strengthen understanding of individual students at different levels. An analysis of the growth during the unit of six target students (Murata, 2002) found that individual students' movement differed from one another, and continuous classroom practice provided supports and opportunities for them to revisit the same concept many times when necessary. While students took time to practice and gained fluency with the BAMT method, the shift occurred that made the method become truly owned and understood by students, each through their own learning path.

### Conclusion

The example of Japanese Grade 1 classroom illustrated a learning environment where students' ideas are valued, opportunities are provided to investigate different ideas and to make connections among them, and much time was given for students of different levels to develop and maintain the ownership of the culturally-valued method taught in the classroom. Although 8 out of 11 lessons were spent for the Phase

Three of the unit, lessons in the last phase often started with the student review of the BAMT method, sometimes with comparison with other methods, guided by the questions of Mr. Otani. Even after most students became familiar with the method, Mr. Otani always helped them review the steps of the method using multiple representations when new addition numbers were introduced in lessons. The unit began with students' sharing of ideas at the beginning, followed by reflection and analysis of different methods, and concluded by students' using and practicing the culturally-valued BAMT method as their own.

## **PROBLEM POSING: WHAT CAN IT TELL US ABOUT STUDENTS' MATHEMATICAL UNDERSTANDING?**

Susan E.B. Pirie  
The "μ-Group"  
University of British Columbia

### **Setting the Scene**

In 2001, at Snowbird, Utah, members of the μ-group<sup>i</sup> from the University of British Columbia, under the guidance of Dr. Susan Pirie, engaged in an innovative, continuous session of linked papers which consider the notion and nature of mathematical understanding and reviewed a number of different theories and approaches to this phenomenon. We presented, discussed and contrasted a variety of key ideas in this area and considered their usefulness and applicability in analysing the mathematical actions of pupils working in school classrooms. We also presented in detail how we undertake our video analysis and for this, the reader is referred to the paper by Pirie in last year's proceedings entitled "Analysis, Lies and Video-tape." This year we intend to use a slightly differently structured session to enable even greater audience participation, especially by those who are unable to attend the entire session. We will still be show-casing the collaborative work of the teachers and mathematics educators who are members of the μ-group, but we will offer an interactive symposium space in which to discuss three papers and three posters, all presented together in one long session. Participants will be invited to examine the presented research, and to enter into dialogue with the authors both as a group and individually.

As part of a SSHRC<sup>ii</sup> funded project into the effects of Problem Posing on ways of understanding mathematics, μ-group members have taken a common mathematical prompt—"If the answer is 72, what is the question?"—to a wide variety of students and explored the mathematical understanding revealed as the students grappled with posing problems from their own, individual, mathematical perspectives that fit the provided situation. Each researcher presented the problem as they saw fit to their students, given the students' level of mathematical knowledge and sophistication

Our session as a whole will encompass papers and posters presented in interactive ways by:

Susan Pirie, with a review of the group's theoretical position and methodological stance;

Katharine Borgen, whose work is with Grade 9 students tackling mathematics in English which is their second language;

Lionel LaCroix, who has taken the common prompt out of the classroom to an industrial-trades worker of 25 years experience of using mathematics in the workplace;

Donna Jenner, who has taught and studied Grade 2/3 students working individually and in small groups.

Shelley Saltzman, who has worked with a small group of Grade 4 students with learning difficulties in mathematics;

Shevy Levy, who approached pairs of students of a wide variety of ages;

Amy Bamford, who challenged her Grade 12, enriched curriculum class.

Lyndon Martin will act as a discussant for the session.

### Theoretical Framework

Since 1987 Thomas Kieren and Susan Pirie have been involved in a collaborative research project to develop, test and refine a theory for the growth of mathematical understanding. Rather than think of understanding in terms of singular (or even multiple) acquisitions, or test for it merely by noticing differences in pre and post instructional behaviours, our theory allows one to observe growth of understanding as a dynamical, non-linear process. It offers a way to examine the cognitive activities of students as they 'come to know' mathematical concepts and therefore also offers the possibility for a fine-grained analysis of the problem-posing process, not so far undertaken.

The theory (Pirie & Kieren 1991, 1994a, 1994b, 1996) posits eight layers of understanding together with the cognitive activity of 'folding back' as crucial to growth of understanding. As illustrated in the figure, these layers each contain all previous understanding and are each contained by all outer more sophisticated understanding. A student's growth of understanding is traced out by a 'back and forth' pathway across the layers. The core of all understanding is one's Primitive Knowing, defined as everything one knows *except* knowledge already created on the particular topic under consideration, which is, of course, understanding at one of the other levels *for that topic*. Three of the inner layers are defined as Image Having, Property Noticing and Formalising. At the Image Having level, for any particular topic, students are observed to hold one or more mental image (often very specific, limited and context dependent) which they

Figure 1. The Pirie-Kieren model for the dynamical growth of mathematical understanding.

are able to employ when working on mathematical tasks. At the Formalising level, students are seen to be working with generalisations of concepts, and they no longer need to relate back to the specific mathematical contexts that gave rise to their understanding. Between these two layers lies that of Property Noticing. Here students are engaged in the reflective activity of examining their images: making distinctions and connections between them. It is this level of cognitive activity that enables students to formalise their mathematical knowledge with comprehension, and it is this level that is so often ignored by advocates of discovery-based learning.

### **Problem Posing**

In mathematics, “problem posing” refers to both the creation of questions in a mathematical context and to the reformulation, for solution, of ill-structured existing problems. Over the past two decades, problem posing has received only sporadic interest within the field of mathematics education, and this focused mainly on students writing story problems in a given context or with given data. Cudmore (2000) tends to show that the value of this work is limited in terms of growth of mathematical understanding. Research has also been largely focused at the elementary grades, and therefore involved comparatively unsophisticated mathematics and questioning. (See a review of the literature by Silver (1994) and more recently work published by Brody and Rosenfield (1996) and English (1997)). To pose mathematical questions at any level, however, involves more than being able to do the mathematics. It requires some understanding of the mathematical concepts involved - at the very least a feel for when a concept can be appropriately invoked. As a part of the SSHRC funded project, Pirie has developed an additional, somewhat more specific meaning for problem posing. We have asked students to pose, or create, mathematical questions in a specific topic area that they have studied, “like the ones you did in the text book” when all they are given is “the answer from the back of the book.” We have hypothesised that learning to problem pose might also enhance students’ learning for understanding. That is to say that, in coming to ask questions on mathematical concepts, students might come to understand those concepts in a more generalised, less context-dependent way.

### **Methodological Stance and Methods of Analysis**

Since the aim of our research is to tease out the “specific structure of occurrences” (Erickson 1986) of problem posing, the methodological approach is an interpretative one, based in case studies and ethnographies, using participant observations, video-stimulated recall techniques, clinical interviews and analysis of students’ written work. Since so little is known about the nature of problem posing as a cognitive activity, such a methodological approach allows us to view the process of data collection as “progressive problem solving, in which issues of sampling, hypothesis generation and hypothesis testing go hand in hand” (Erickson 1986). This approach enables decisions of which cases to focus on to be taken as the research progresses and we are building a “portfolio” of examples of growth of mathematical understanding that illustrate learn-

ers working at the Property Noticing level. Pirie's specific form of problem posing is proving very productive in providing evidence of work at this level.

Each of the researchers videoed their students "problem posing" and used multimedia techniques, mainly based around VPrism software, to assist in the analysis of the data from the perspective of the mathematical understanding revealed by the students through use of the "answer is 72" starting situation. As can be imagined, some very different and interesting features have emerged from the research and these will all be open for discussion at the session.

### The Portfolio

There is clear evidence from our data (and that of many others) of a disconnected mental leap that many students are required to make as they move from having constructed some mental image(s) of a concept, to its formal representation, without having grasped the relationships and features of their images that enable this abstract generalisation of their concrete experiences. This transition between levels of understanding is not well understood by the mathematics education community. Action and discovery learning, while enabling students to form richer mental images for mathematical concepts, have failed to provide the link, that many students lack, between action-tied images and generalised formalism. Asking students to pose mathematical problems within a given topic, rather than to answer well constructed teacher/text questions, appears to provide a much needed, connective bridge to formal generalisation with understanding.

The specific form of problem posing that we are using currently was developed out of an incident where students were working from a standard text book, with questions in the topic of quadratic equations such as: Solve  $5x^2 + 3x + 0.25 = 0$ , which

simply needs students to remember the formula  $x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$ . A question posed

by one of the students in the class, however, - "Why does 3.5 'solve' that equation?" - led to a class discussion around the meaning of "solve" in this context and what the formula was actually 'doing'. From this Pirie constructed the question:

"If the page giving the exercise had been torn from your text book, but you still had the answers at the back of the book could you reconstruct the quadratic equations? For example, if for question (1) the solution was 3.5, what was the quadratic equation?"

This notion of giving students an answer in a specific mathematical context, and expecting them to create a "standard" question to fit it was then expanded to other topics. This is proving to be a very effective method of provoking learners to think at the Property Noticing level in order to connect the images for the topic that they have built up, with the formalisations that they have been using to answer the questions in the text book exercises.

The rest of the contributors to this  $\mu$ -group presentation will illustrate, using a few of the examples in the portfolio, the widely differing ways in which a single prompt

can provoke or reveal growth of understanding at a whole range of ability and topic levels.

## PROBLEM POSING IN A SECOND LANGUAGE

Katharine L. Borgen  
kborgen@interchange.ubc.ca

Mathematics has often been considered "language free." At the same time, problem solving and problem posing are considered appropriate means of determining students' conceptual understanding of mathematics. This article considers the working of four relatively capable mathematics students in Sweden, whose *primitive knowing* was developed in Swedish, who were asked to pose a problem in English. Results indicate that for these students, an obstacle to their ability to express their mathematical understanding was their need to concentrate on the correct grammatical presentation of their work. This distracted from their concentration on the mathematical presentation, possibly making them look less capable.

An individual's first language is the language through which he/she initially perceives the environment, through which first concepts are developed, and through which identity as a person is achieved (Pattanayak, 1986). While many consider that mathematics is an absolute with universal symbols, making language less important in the understanding of it than in other subjects, mathematics has a very precise language with subject specific meanings that are often combined with symbolic notation (Scholnick, 1988; Mestre, 1988; Lass, 1988; Kimball, 1990). The ability to express oneself mathematically requires logical and abstract thinking (van Heile, 1986).

Due to the considerable amount of immigration around the world, the language of communication in the classroom is often not the first language of the student, or even the language spoken in the home. While students who come from a home where English is the language of communication will be aware of, although probably unconsciously, the linguistic structures that affect meaning, this is not necessarily true for second language learners. Thus, while many second language students are placed in a regular mathematics class long before they are placed in a regular class where language is thought to be more significant, they may lack knowledge of the linguistic structure that gives meaning to the expressions encountered in the mathematics classroom (Cuevas, 1991), possibly placing them at a cognitive disadvantage.

Standards based mathematics promote sense making by being comprehensive and by developing ideas in depth in a coherent and motivating manner (Taftan, Ryes & Wasman, 2001). The 2000 National Council of Teachers of Mathematics (NCTM) Standards have stressed the importance of conceptual understanding in mathematics as a component of proficiency. This implies an understanding that is beyond the simple manipulation of symbols, allowing, and even requiring, students to express their understanding verbally. However, teachers often find that, while students may be able to perform the mathematical algorithms appropriately, they often struggle in

their attempt to describe the mathematics they have done or to explain why they used a particular approach. This inability to verbalize their procedures may not necessarily indicate a lack of conceptual understanding, but rather, may be due to the abstractness and theoretical nature of many mathematical concepts (Miller, 1993).

When students work at mathematics in a language that is not their first language and which is not the language spoken at home, the ability to express their understanding is even more of a problem than for first language students because they often “think” the mathematics in their first language (Borgen, 1998). Thus, when second language students seems to perform less well than first language students, it may be that they simply lack the linguistic ability to express their cognitive understanding (MacGregor, 1993; Adler, 1995). In order to put the mathematics into context, they must, to borrow an expression from the Pirie and Kieren (1994), *fold back* to terminology and images formed and described in their first language, and may attempt to transpose and translate these to the new situation. Attempts at translations may not help as direct translation seldom, if ever, provides the same meaning as the original expression. Also, the students might not have encountered the relevant mathematical terminology in their first language. Translation may thus create disjoint connections between cognition and verbal expression, a discontinuity of ideas from one language to the other. So, when second language students are asked to express their mathematical understanding, even though they may have learned the requisite terminology in the second language, they may simply be unable to verbalize their thoughts because the foundational concepts are understood in their first language. Discussion of the new material cannot therefore take place in a coherent manner.

The emphasis on understanding being placed on mathematics by NCTM Standards has lead to an increased emphasis on problem solving. This, of necessity, requires understanding of the language and of the context of the question. The area of problem solving, therefore, is one in which second language learners often have difficulty. They thus often rely on patterning solutions based on problems previously done in class (Borgen, 1998).

Problem posing is often seen as a means by which students can display their level of understanding of a mathematical concept. In forming a question for which the answer is known, it is often assumed that students can display their understanding more clearly than if they are simply asked to solve a question.

This paper will consider a problem posing situation involving students for whom English is not their first language. I will consider the question they created and their solution to it, although the two do not agree, and discuss the effect that using a second language might have had in the problem-posing situation.

Answer is 72: What is the Question?

### **The Swedish Setting**

The setting for this study was Umea, a medium sized city in the northern part of Sweden. Four grade nine students, Klara, Stine, Nathaniel and Maria, agreed to take

part in a videotaped session. It is important to note that in Sweden, the use of English as a language for communication is promoted in many ways. In most schools, in the first grade, students learn songs, colours and some useful words. By grade four they start a more formal approach by learning to read and write in English (S.-M. Kuoppa, personal communication, 2002). Most television programs imported from English speaking countries are not dubbed, as is the norm in many European countries, but rather are presented in English with Swedish subtitles. And, although Sweden has a strong rock and pop culture of its own, not only are North American pop songs widely circulated and listened to, as far back as the early 1970's the well known Swedish rock group, ABBA, recorded in English as have, more recently, Ace of Base and Roxette, to name a few. Swedish Metal bands that record in English include In Flames, Children of Bottom, Opeth and many more. Thus, most Swedish people have been exposed to the English language on many levels, and, by the time students are in grade nine, they appear fluent in oral English.

### **The Problem Posing Session**

When I met the four students involved in this session, I spoke to them briefly to ascertain their level of English and to explain what was planned during the session. As expected, their understanding of English, and their ability to express themselves in it created no major obstacle. I explained to them that I was from the University of British Columbia and that I was part of the MU Group, a research team of teachers, university students and professors who were interested in mathematical understanding and that we were presently working on a particular aspect of that understanding. Specifically, we were interested in something called "problem posing." Therefore, in this session, I would not give them a question, but rather, I would give them a solution and they would be asked to create a question that suited it. The catch was, however, that my particular interest was in mathematical understanding in a second language. Therefore, I was asking them to create and discuss the question in English as much as possible. However, if at any point they could not find the expression they needed in English, they should naturally speak in Swedish. I had made the assumption that since they had learned mathematics in Swedish their primitive knowing (Pirie & Kieren, 1994) would be in Swedish, that they might not know all the appropriate English terms, and that they might need to use each other as "sounding boards", knowing what they wanted to say (in Swedish) but not knowing how to express it (in English).

I had had a chance to peruse the textbook that the students had been using to determine what work they had covered during the year. Although I could not read Swedish, I was able to ascertain the gist of what they had done by the mathematical symbolism. I had also talked with the teacher who indicated that the most recently covered unit was a review of fractions. I therefore suggested to the students that they could use this as a start, or they could choose any area of mathematics where they thought they could come up with a suitable question. Thus, the students began their solution, or question making, by discussing a setting in which Ana and Alex buy some apples. They briefly

considered a scenario in which one person buys more apples than another. Klara then suggested that they should come up with “the mathematic (sic)” first, and then make the “problem.” The students briefly discussed the format the “equation” should take. (In transcriptions, **bolding** is used to indicate that words were stressed orally, --- for a pause, and ... to indicate missing sections.)

*Klara: Well, if we should come up with like the mathematic, the mathematic problem first then it, then put it in the words.*

*Klara: Maybe we can, so if the answer is seventy-two. We can have like --- seventy-two something times something divided by something and the answer is something and then you have to count out what, what  $x$  is and  $x$  will be seventy-two.*

*Maria: Uh hu*

*Klara: Do you get it?*

*Nathaniel: Yeah*

*Klara: So, uh,  $x$  is seventy-two. OK, seventy-two, then we can have seventy-two times something that works. --- Seventy-two times --- Four maybe? Or four --- OK seventy-two then its  $x$  times four and that is two hundred and eighty-eight. Two hundred eighty-eight. That's divided by ---*

*Stine: Two hundred eighty eight*

*Maria: It could be like Ana buys*

*Nathaniel: Its divided in four you get seven --- You get --- no*

*Klara: No, but if you divide in four you get seventy-two. And that's the answer, but*

*Nathaniel: Yeah, I know, I know*

*Klara: Uhm if you divide it by --- maybe --- six you get forty-eight, so if it is  $x$  times four divided by six equals forty-eight, what is  $x$ ?*

*Maria: Uh hu.*

*Nathaniel: Seventy-two*

The students thus formed their “equation” and went on to form a problem using this form as their solution. The students’ decision regarding the format of this “equation”, it seems, dictated their thinking about the problem, and they considered it as the solution. The actual problem they created did not agree with the solution they had predetermined. Specifically, the problem the students posed and their solution are presented in Figure 2.

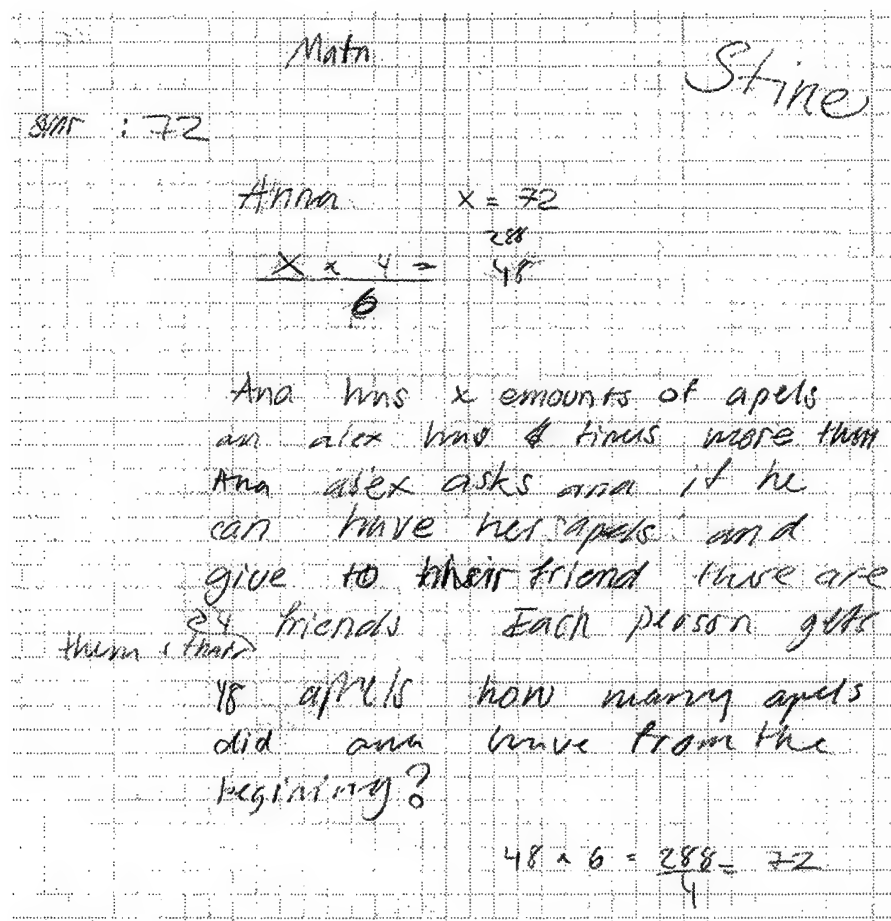

Figure 2. Problem posed by the students.

Rather than transcribe the entire discussion, in this next section I will state some of the inferences I made with respect to the students' performance of mathematics using English as their language of communication and will give the transcription of only those statements that prompted me to arrive at these inferences.

### Inferences

The problem posed was a mere "copy" of problems from previous mathematics work. Little creativity went into formatting the question. The students had decided that they would form a "word" problem and discussed how to form it:

Nathaniel: We gotta write a problem and solve.

Klara: Mmmm. Well should we like --- apples and that's x and that times something is seventy-two or shall we do like another ---

...

Stine: We ca --- They always --- Ana and Steve always bla bla bla and umm umm umm are going to give us some apples. (At this, all the students laughed.)

Later, they specifically indicated that they had simply formulated a question similar to those that they were accustomed to doing.

*Nathaniel: We make like example from the book. They are all ---*

*Klara: They are always taking Ana. They have to divide apples or potatoes or whatever.*

It is unclear whether they would have been more creative if they had been asked to form a question in Swedish. However, what is apparent that they simply used an existing model to format their ideas – that they felt that this was a suitable type of question to form in a mathematics class.

The students, it seems, needed a mathematical model and only then could they make a problem (albeit incorrect) around this “equation.” As noted earlier, Klara had indicated that they come up with the mathematics first, and then created a situation in which the equation  $4x/6=48$  applied. Following was a set of disjoint statements in which the students seemed to be trying to formulate their thoughts as to how the question could be worded.

*Klara: ... But then you have to have like Ana has  $x$  amount of apples --- and uh*

*Nathaniel: Times five by four times more*

*Klara: No, like Alex has four times more than Ana*

*Nathaniel: How much?*

*Klara: Ans --- so maybe*

*Nathaniel: And then they*

*Klara: And then they ---*

*Stine: So they put them together and [She swore in English](laughter)*

*Nathaniel: Well, if we do like and they put them together*

*Klara: Ana. Put them together and divided by divided by six*

*Nathaniel by six persons*

*Klara: Yes, by six, by six persons*

*Nathaniel: By? And how, yeah, and how how many apples*

*Klara: Does Ana have, yeah*

Few, if any, theoretical mathematics concepts were expressed during the problem posing session. The students simply tried to state a problem that suited their “equation.”

Correct grammar seemed more important than correct mathematics. Once the format of both the equation and the problem were outlined, the students continued to

discuss the actual situation, but concentrated more on the grammatical structure of the problem they were creating than on the mathematics involved, being sure that numbers and tenses agreed.

*Klara: So that's Alex asks Ana, asks Ana if he can have hers --- hers and divide them --- to her, and give --- give to his friends.*

*Nathaniel: And give them to his friends*

*Klara: And give to his friends*

*Nathaniel: Six friends*

*Klara: Or, to give to his friends. For hers to*

*Nathaniel: Hers apples*

*Three girls: Her apples*

*Nathaniel: Her, I mean*

*Klara: Give it to her his um ... And together Alex and his friends are --- Alex's five friends*

*Maria: Yeah. Are divided them*

*Klara: along if if five friends, then he gets some, too. Or maybe there are four friends and they divided by*

*Maria: by friends.*

*Klara: And by their friends, not her friends, not his friends, his friends, umm her friends, their friends.*

*Nathaniel: Their friends are four*

*Klara: Their four friends. Or maybe just like them and their friends --- them and their friends --- and their four friends*

She again corrected Nathaniel.

*Nathaniel: Alex asked Ana if he can have her apples and give to his four friends."*

*Klara: And give to their.*

In these latter two incidents, Klara seemed to be making sure that the grammar was appropriate to the numbers. Later she also corrected herself from "did Ana had" to "did Ana have," showing a concentration on tense, thus the importance of grammar.

Once the "equation" was formed, the students considered it the solution to the problem they had posed without considering how they would actually do the problem had it been presented to them. No thought was given to the relationship between the

problem (words) and the mathematics (equation). When asked to find the solution to the question they had created, Klara read the question (not verbatim).

*Klara: Ana has  $x$  amounts of apples and Alex has four times more than*

*Ana. And Alex asks Ana if he can have her apples and so they can divide them to **their** four friends also. And so then each person, when they have divided them, each um gets forty-eight apples. How many apples did Ana have from the beginning?--- So then you take forty-eight that everyone gets times six 'cause there are six persons. Then you get [uses calculator] two hundred and eighty-eight. Yeah. And two hundred and eighty-eight divided by four, 'cause you got Ana's ... four that's around*

*Nathaniel: Divided by four is. Divided by four is seventy-two. So we have the answer that is seventy-two*

*Klara: Ana has seventy-two apples from the beginning. Ta da*

During this conversation, all four wrote down the solution as they had discussed it in their posing situation. They did not realize that their working and solution did not match the problem that they had posed. Notice that Klara had to clarify again in her mind that there were six people, and stated the four "'cause you got Ana's." However, she did not identify the fact that Ana had  $x$  apples, and it was Alex who had four times more, or that, when they were put together, there would be  $5x$  apples. Thus, the students did not really rework the problem, but simply used the numbers that they knew.

Again, it is unclear whether this was due to the use of a second language, forcing them to concentrate on the linguistic structure of the problem created, or because they already "knew" the process or equation through which they got the solution. This area of the research needs more study in other situations and should be compared to similar posing situations for first language students.

### Discussion

The students involved in this discussion were described by their teacher as being mathematically able and seemed to have a good command of the second language, English, in which they were asked to pose a question. However, their *primitive knowing* (Pirie & Kieren, 1994) was constructed through learning in Swedish. Although they had been advised that they could use Swedish in their discussion if it helped them clarify their meaning, they did not feel the necessity to do so. It seems that there were no situations in which they felt that they could not express themselves adequately in English. They concentrated more on the language of presentation than on the mathematical presentation, seeming to want to be sure the problem was grammatically correct. The result was a solution that did not agree with the actual problem posed. It agreed with their original "equation" and did not consider the details they inserted

into the problem, nor was the problem at all creative. It was simply a copy of a typical textbook problem. It may be that, since the students had been taught mathematics in Swedish, they had not encountered more complex mathematical terms in English, so that their ability to express themselves was limited to the terminology and concepts that they understood in English. It could also be that their concentration on the correct grammatical presentation deterred them from concentrating on the mathematics.

While one must be careful not to take the situation out of context or to generalize from one case, one must still consider the similarities between this situation and the situation of students new to a country where the language of the classroom is not the student's first language. Many of the students placed in an English speaking mathematics classroom in North America have a much poorer command of the English language than do these students. Learning to converse in a second language requires approximately two years of extensive exposure, while learning to communicate technically requires closer to seven years (Cummins, 1979). Thus, for second language learners, concentration on the correct use of language (conversation) may detract from their ability to concentrate on the mathematics involved (technical). Understanding mathematics involves an interplay of conceptualizations and verbalizations that must be meshed together to create meaning. If the languages of the two (conceptualization and verbalization) are different, the verbalization, the need to understand and be understood, and the need to express oneself as appropriately as possible, may take precedence over the conceptualization. In concentrating on the language, students may not be able to attend to the mathematics.

In a problem-posing situation, the linguistic structure of the problem being posed, as they are trying to make meaning of the language used as well as the mathematics involved, may be of greater significance to second language students than the mathematical structure of the problem and its solution. Therefore, problem posing may not be a suitable method for determining their level of mathematical understanding.

### **A TRADESMAN'S MATHEMATICS UNDERSTANDING IN A MACHINE SHOP: INSIGHTS PROVIDED BY THE PIRIE-KIEREN THEORY**

Lionel N. LaCroix  
lionellacroix@sympatico.ca

This case study examines the understanding of ratio used on the job by a successful tradesman as he designed and built a milling machine gear mechanism. The tradesman had limited formal mathematics and technical training and in problem solving he made extensive use of hands-on materials, trial and error and the freedom to try out an answer and modify it as needed. Using the Pirie-Kieren theory of mathematical understanding, it was determined that the tradesman worked at the levels of image making, image having and property noticing. The power and utility of these problem

solving methods evident in this study and, from the perspective of the Pirie-Kieren theory, the necessity to work through these levels of understanding in the process of developing the higher levels of understanding associated with the school mathematics challenges the authenticity and validity of much of what is done in schools in the name of developing students' understanding of mathematics and teaching students to become problem solvers.

This case study examines some of the mathematics understandings used by a tradesman in solving problems encountered in his work. This individual is of particular interest in that, while highly regarded for his expertise within his industry, his formal mathematics and formal industrial training have been minimal—he developed the vast majority of his technical knowledge on the job in a variety of industries over his career, and he has been self employed and working independently in his own machine shop for most of the past 25 years. (The participant, now 81 years of age, began working full time at age 14 in a garage after receiving three years of elementary school education.) Thus, many of his mathematical understandings and problem solving methods have been constructed in response to particular problems encountered on the job, making use of the tools and equipment at hand, and reflect a limited degree of prescribed school taught methods. It should be noted that a minimum of research has been published which focuses on the mathematics and problem solving performed on the job in an industrial setting. (e.g., Scribner, 1984a, 1984b, 1984c) It is also the purpose of this study to examine the usefulness of a type of novel and open-ended question to initiate dialogue with an individual for the purpose of revealing mathematics understanding. The particular question used in this study was, “The answer is 72, what is the question?”

Mathematical understanding was examined in this interpretive case study through the lens of the Pirie-Kieren dynamical theory of mathematical understanding (Pirie & Kieren, 1994). In comparison with situated cognition, for example, which focuses on identifying and comparing mathematics practices in different settings, the Pirie-Kieren theory facilitates the analysis of even brief mathematics problem solving episodes in terms of a developmental perspective of individual mathematical understandings.

The volunteer subject was interviewed over a number of days in his workplace and asked to talk about his use of mathematics and problems that he solved in his work. These exploratory discussions were initiated, in part, using the question indicated above. On the basis of what was said, further questions were created *in situ* and posed by the researcher to encourage the participant to elaborate on the types of problems that he solved and the use of mathematics in his work, his ideas and his methods for performing these and his criteria for assessing the appropriateness of his methods and results.

Audio recordings of the interviews, all written work produced by the participant, photocopies of printed reference materials cited and photographs of artefacts referred to during the discussions were retained for analysis. These data sources were reviewed

by the researcher, significant episodes were identified and coded in the interview dialogue, and verbatim transcripts were constructed of many of these episodes. All of these information sources were then used in concert to construct the case description. Finally, the conclusions constructed by the researcher were shared with and validated in further discussion with the tradesman himself.

A number of features of this man's use of mathematics and mathematical problem solving figured prominently in the discussions. These included the use of charts for useful numerical data and unit of measure conversions, the use of various specialized measuring tools, the use of tools and machinery in the problem solving process, the use of standardized and prefabricated components when building things, and the use of conventions and "rules of thumb" specific to machining. In all cases the appropriateness of his work was tested empirically—did it do the job?

For the first interview, the tradesman brought and presented a number of charts that he used on a regular basis. He explained that he didn't really do much math on the job, instead he relied on these charts and others like them in his machinist's handbook. A number of these charts were posted prominently on the walls in both the machine shop and office work area. The charts that he brought included: industry standard drill sizes in inches to three decimal places and the drill sizes needed for tapping holes of different sizes (i.e., making a thread within a hole for a bolt), measurements for standard male threads of different sizes, the dimensions for various shapes and sizes of steel bars available for the manufacturing process, the dimensions for locating between five and 12 holes equidistant around a unit circle, recommended torque values for fastening bolts of various sizes and various metal strengths, the required lathe settings to create standard sized threads, and a standard trig table which included the formulas for determining all possible unknown values within a right triangle given one side length and one other piece of information. It was the tradesman's view that if you didn't have the required information at hand, you could always look it up in a machinist's handbook or equipment manual. In a subsequent discussion, the tradesman agreed with the researcher's conclusion that using these charts minimized the need to perform multi-step calculations, use formulas and perform any form of algebraic manipulation.

Throughout the interviews the tradesman also explained how he used specialized tools and/or equipment for: measuring the thickness or diameter of an object to the nearest ten thousandth of an inch, measuring the depth of machine treads (used in conjunction with a special chart), setting material to be machined at a predetermined and precise angle of inclination in a vice, precisely rotating and securing a work piece to be machined using specialized chuck, as well as how he used the digital readouts on a number of his machines to locate the center of a piece of work, to the nearest thousandth of an inch, by taking an average of the co-ordinates of the outer edges, and how he used these same digital readouts for converting between imperial and metric measures of length. Like the charts described in the paragraph above, the tradesman

used specialized tools and his shop equipment to perform routine mathematics tasks in ways which simplified his work and minimized his effort.

Another prominent part of the discussion related to conventions or “rules of thumb” and the use of available standard or prefabricated tools and components in his work. On technical drawings for example, dimensions given in decimal form were understood to be accurate to a thousandth of an inch with tolerances of plus/minus “a thou”—the standard unit of measure for amounts less than an inch. Decimal values of tenths, hundredths and ten thousandths of an inch were all expressed in terms of thousandths of an inch. Dimensions given on technical drawings in fraction form were understood to have tolerances of plus/minus  $1/64$  of an inch or plus/minus 15 thou. (Author’s note,  $1/64 = 0.015625$ ) When cutting steel on a band saw a rule of thumb for selecting the right type of saw blade was that ratio of teeth on the blade to thickness of the material be no less than one and a half to one. This was to prevent the work from vibrating as it was being cut. And, when cutting a keyway slot in a hole (for securing a gear or wheel onto an axle), the width of the slot depended upon the standard sized cutters that were available to do the job and it was a rule of thumb that the depth of the keyway slot was half of it’s width. Threads were always cut using standard metric or imperial thread sizes because of the tools and equipment used to perform these tasks, pre-existing and standard material sizes and prefabricated components were routinely used or modified for use in the design of objects to simplify the manufacturing process. And lastly, all of the cutting, milling, drilling and grinding operations could only be performed as permitted by the machinery available. The effect of these practices was to set a highly codified context in which problem solutions were conceptualized. For example, when approached about building a specialized latch for a garden gate, the tradesman’s first response was to reframe the proposed design in terms of the material and components that he currently had in stock, and in terms of standard sizes and standard machine operations.

Unlike school mathematics or school problem solving where the answer is at the back of the book or the teacher is the arbiter of solution correctness, the tradesman was able to test the appropriateness of his efforts by trying them out and checking to see if they functioned as they were supposed to, and in the end they always did! Whenever a design did not meet the intended criteria, this indicated simply that the process was not yet finished. In fact, it was not uncommon for a client to return after a job had been completed requesting that further modifications be made to the device that had been made because new ideas arose from seeing it and using it.

### **If the answer is 72, what’s the question?**

When asked what question could be answered in his work with the answer 72 the tradesman, after an extremely long pause, explained that three of the gears, in a complex gear mechanism that he designed and built some years earlier for manufacturing hand reamers on his milling machine, each had 72 teeth. A reamer is a tool used for

shaving off a minute amount of metal inside of a hole to make it a precise size after it has been drilled, or to resize a hole precisely after it has become worn. To make reamers, pieces of round bar are first cut to length and small center holes are drilled in each end to a depth of approximately a quarter of an inch. These pieces are then held by their center holes and passed lengthways through a rotating cutter on a milling machine to make between six and twelve evenly spaced indentations or "flutes" in the reamer between four and a half and five inches in length at one end. The reamers are then hardened and the metal which remains between the flutes is then ground to an exact size to serve as cutting blades. A large portion of the interview time was then spent discussing the design criteria and construction of the gear mechanism used on the milling machine in this manufacturing process.

The gear mechanism was designed in order to perform three operations for milling reamers of different sizes: 1) to allow for the reamers to be rotated or "indexed" on their center axes after each pass through the cutter so that a predetermined number of flutes could be cut, 2) to rotate the reamers slightly as they passed through the cutters to produce a helix or spiral cut pattern in the flutes and to adjust the degree of rotation for different sizes of reamers, and 3) to hold, index and rotate up to four reamers at a time for simultaneous machining. The power to the gear mechanism was fed from a shaft on the table of the milling machine.

The tradesman explained that when he designed the gear mechanism he drew upon his experience using various combinations of gears--which he changed manually on an old lathe in order to cut helical threads. He had often used a gear with 72 teeth with various smaller gears to reduce the speeds on the lathe. He chose to use three 72 tooth gears with three smaller gears in the gear mechanism for his milling machine to obtain the slow rotation needed for turning the reamers as they passed through the cutter. The choice of 72 tooth gears in particular allowed for simple gear ratios with many different sizes of small gears, these particular gears met the size and strength requirements of the job and by choosing three gears of the same size he would need only to design and build one kind of bracket to hold each of them in place. The 72 tooth gears were paired with of a 16 tooth, a 36 tooth and an 18 tooth gear which the tradesman explained "all divided 72 evenly." He explained further,

My math wasn't that great, that I could figure things out in advance, to come to the exact ratio.... I wasn't interested in accuracy, where one or two teeth would make a difference, but I had to be in a certain range. I assembled a couple of them and then checked the results and then assembled one more and then I made a note of it, it was a matter of trial and error. This was pretty much the process.

Two other gears were needed to complete the mechanism, one at the beginning of the gear sequence and one near the end. Initially two specific gears were selected to provide the appropriate rate of rotation of the reamer to produce the helical pattern

| Size    | Flutes | Power Gear | 1 <sup>st</sup> Stud | 2 <sup>nd</sup> Stud | 3 <sup>rd</sup> Stud | Spindle Gear | Index turns |
|---------|--------|------------|----------------------|----------------------|----------------------|--------------|-------------|
| 1/4" up | 6      | 27         | 72/18                | 72                   | 72/16                | 48           | 1/2         |
| 7/16"   | 6      | 24         | 72/18                | 72                   | 72/16                | 48           | 1/2         |
| 1/2"    | 8      | 24         | 72/18                | 72                   | 72/16                | 64           | 1/2         |
| 5/8"    | 8      | 36         | 72/18                | 72/36                | 72/16                | 64           | 1/2         |
| 11/16"  | 8      | 27         | 72/18                | 72/36                | 72/16                | 64           | 1/2         |
| 1 1/8"  | 8      | 24         | 72/18                | 72/36                | 72/16                | 64           | 1/2         |
| 1 5/16" | 10     | 27         | 72/18                | 72/36                | 72/16                | 80           | 1/2         |
| 1 3/4"  | 12     | 18         | 72/18                | 72/36                | 72/16                | 64           | 3/4         |

Figure 3. The gear configurations for machining various sizes of reamers.

needed for a one inch reamer and to allow for the indexing required to make eight flutes. Then over a period of many months, other gears were purchased, one or two at a time, for use in the beginning and end positions of the gear sequence to obtain the spiral patterns required for reamers ranging in diameter from one quarter of an inch to one and three quarter inches for reamers with six to twelve flutes. The specific combinations of gears that worked best were then recorded on a chart for future reference. A recreation of this chart is included here as Figure 3. When asked if, at the start of the design process, he was sure that the speed reduction and spiral cut features of the gear mechanism would work as needed using the initial three pairs of gears, the tradesman answered "No. Probably 80 percent sure."

When asked about how well his gear mechanism worked for making reamers of different sizes, the tradesman explained that, "I ran into some problems with the one and one eighth inch reamer. I still haven't figured out how to give it enough spiral on the flute. It's not quite enough. There's enough to get by. It's not that critical."

The tradesman was asked if he could relate the numbers on the gear combination chart for the gear mechanism. To get at this the researcher posed the question, "If part of this chart was missing, could you use the existing numbers on the chart to figure out the missing ones?" He responded by explaining that he would set the machine up with a finished reamer in place and observe how it moved using different combinations of the gears until he found the combination which gave the required indexing and spiral.

### Assessment of Mathematical Understandings

The focus of this analysis is the tradesman's understanding of ratio as evidenced in his description of designing and building the gear mechanism for his milling machine and, as mentioned earlier, mathematical understandings evident during the interviews were assessed using the Pirie-Kieren theory. In order to make the case that the tradesman was able to work at least to the level of property noticing, evidence for the levels leading up to and including this level will be presented in turn.

The level of image making was evident when the tradesman tried different combinations of gears to adjust the speeds of both his lathe and milling machine, and when he worked with different combinations of gears by hand, counting the resultant number of turns of the small gears for each turn of a 72 tooth gear. The level of image having was evident when the tradesman commented that linking 16, 18 and 36 tooth gears with 72 tooth gears all resulted in simple gear ratios because these numbers "all divided 72 evenly." Finally, the level of property noticing (specifically the property of equivalent ratio) was evident when the tradesman responded that a 90-30 gear combination would act the same way as a 72-24 combination when he was asked why he chose to work with 72 tooth gears instead of, for example a 90 tooth gear attached to a 30 tooth gear. When asked about the possibility of using other gear combinations, he explained that a 36-18 gear combination would work in the same way as a 72-36 combination. Elsewhere the tradesman explained that linking a large gear with a small gear would reduce the speed in a machine and that the larger the difference in size, the greater the change in speed.

There was no direct evidence of the level of formalizing. At this level, a research subject is able to abstract a method or common quality from his previous image dependent know how and would be ready for, capable of enunciating and capable of appreciating a formal mathematical definition or algorithm. It is unknown whether or not the tradesman was ready for this as it did not arise as a part of the conversation. It is this researcher's conjecture that the tradesman would be able to follow and appreciate a formal mathematical explanation of his gear mechanism, but this remains only strong hunch.

It is asserted that the tradesman did not work at level six, that of observing at which a research subject is able to reflect upon and co-ordinate formal activity and express patterns as theorems. When asked if he had a way to relate the numbers on the gear chart, he could not without deferring or "folding back" to actually using the gear mechanism with a reamer which is the level of image making. The process of folding back, which is vital to the growth of understanding, is a crucial feature of the Pirie-Kieren theory.

### **Using the Question, "If the answer is 72, what is the question?"**

It appears that the researcher had luck on his side when he posed this question to the tradesman. The number 72 had come up in the interview a few minutes earlier when the tradesman showed the gear configuration chart for the gear mechanism to the researcher. When asked if he could think of another question from his work with 72 as the answer, the tradesman could not. A review of all of the printed material from the interviews did not reveal any other meaningful instances of the number 72 and the tradesman reported that measurements of 72 thousandths of an inch and 72 inches were very unusual in the kind of work that he did. And, when asked what other number might make this question more meaningful for him, he picked things that were

constant terms in his calculations, specifically  $\pi$  and diameter--a value typically given or known in this man's work, not something to be determined. His response to this latter type of open ended question for revealing mathematics understanding appears to relate to the context specific way that this tradesman used mathematics and solved problems.

### Conclusion

The mathematical understandings revealed in this real-world and authentic problem solving context are significant for a number of reasons. First, little detail is known about the kind of mathematics and mathematical problem solving that is done in industrial settings such as a machine shop. These findings provide evidence that that a tradesman can work effectively, at least some of the time, with little formal mathematics. Second, the context in which this tradesman solved problems, specifically with outcomes that he valued highly (i.e., the desire to get the job done) and a need to be self reliant stands in marked contrast to the context in which mathematics and mathematical problem solving are done in a mathematics classroom. It is reasonable to conclude that these non-mathematical dimensions of problem solving contributed greatly to the tradesman's persistence as a reflective problem solver, which ultimately has led to his effectiveness without the need for more sophisticated understandings of mathematics. And lastly, the viability of the methods that were developed and used successfully in this setting, namely the use of hands-on materials, trial and error and the freedom to try out an answer and modify it as needed reveal the power and utility of these methods for problem solving. These methods are seldom allowed in school classroom, and yet an individual can use them to solve complex problems effectively. Furthermore, the Pirie-Kieren theory indicates that these types of activities, which were associated with the image making, image having and property noticing levels of mathematical understanding, are essential in the development of higher levels of mathematical understanding customarily associated with school mathematics. This finding challenges the authenticity and validity of much of what is done in schools in the name of developing students' understanding of mathematics and teaching students to become problem solvers.

It is clear that further research on the use of mathematics in industry would further our understanding of the development of mathematics understanding beyond the classroom; the connections, or lack thereof, between classroom mathematics and the workplace; and the design and implementation of mathematics curriculum, particularly for students who may enter a technical field when they finish school.

## STORIES OF "72"

Donna M. Jenner  
donnajenner@shaw.ca

This study illuminates the rich, flexible ways in which primary children search for and access current knowledge of number or further develop their mathematical understanding of number while working on a novel problem task. A group of four grade Two and Three was videotaped as they developed a question or task where the answer is 72. The seventy minute videotape was then analyzed using the Pirie-Kieren theory and model for the Dynamical Growth of Mathematical Understanding (Pirie & Kieren, 1994a). Two aspects of the theory, folding back and primitive knowing were useful in describing and analyzing the children's actions. The notion of 'interventions' provided a powerful vehicle for considering how the actions and interactions of the teacher occasion the emergence of mathematical understanding. The notion of story as articulated by Borasi, Sheedy & Seigel (1990) was also useful in describing and analyzing how the idea of story impacted how the children approached and develop their problem solutions of stories.

By focusing the lens on a group of four children, this study illuminates the ways in which some primary children search for and access current knowledge of number or further develop their mathematical understanding of number while working on a novel problem task. This study is part of a larger research project headed by Dr. Susan Pirie that is focused on the individual's growth of mathematical understanding in diverse settings. In developing an analysis of the students' activity, the paper draws on elements of the Pirie-Kieren theory for the growth of mathematical understanding and on the power of story in developing children's mathematical understanding as elaborated by Borasi et al. (1990).

The class and the small group were videotaped as the children worked on a task that asked them to create a question for a given answer of 72. The children were taped and observed during the seventy-minute session and the author took some field notes. The notes are brief however, as the author is also the classroom teacher who is seen on the tape interacting with the featured group of four students. This is a mixed ability, combined Grade Two and Three class consisting of 11 Grade Three and 10 Grade Two students. All the children were asked to record their thinking on paper about the question related to an answer of 72. The videotape is focused on four students, three Grade Three and one Grade Two children as they discuss their understanding of the number 72 and how to create a question where the answer is 72. Like the rest of the class, this group recorded their personal approach on paper. The class has engaged in a variety of tasks in the previous months through calendar math, specific activities and explorations designed to develop their knowledge and understanding of number in flexible ways. In other classrooms in previous years, the children became used to seeing and solving story problems where all the information is included in the story and solving means to merely use the given information. These experiences with the typical story

problem form an obstacle in this atypical problem situation. Now they are asked to invent the information for the story. 72 is not part of the story but is its resolution. On the previous day, the children and myself informally discussed how many different questions we could ask someone where the answer is 25. During this discussion it became apparent that the concept of question was very difficult for them to use in a practical way. Many of their responses were equations that “equaled” 25. I began using the phrases ‘story question’ and ‘task question’ as a way to focus their thinking on how to create a question that did not include the answer of 25. This same language was used to pose “the answer is 72, what is the question?” task on the following day.

In order to analyze the students’ mathematical understanding of number, use was made of the Pirie-Kieren theory and model for the Dynamical Growth of Mathematical Understanding (Pirie & Kieren, 1994a). This theory has been presented and discussed at a number of previous PME and PME-NA meetings (see for example Pirie & Kieren, 1992; Martin, Towers, & Pirie, 2000). The Pirie-Kieren theory provides a way to analyze, describe and account for the growing understandings of individual learners of mathematics and, through the notion of ‘interventions’, provides a powerful vehicle for considering how the actions and interactions of the teacher occasions the emergence of mathematical understanding. Two aspects of the theory, folding back and primitive knowing were useful in describing and analyzing the children’s actions. Primitive knowing refers to the mental images a child “holds in her head” when approaching a new mathematical task. Folding back describes how the learner, when faced with a novel question or task that is not immediately resolvable, will return to an inner level of understanding (like primitive knowing) for concepts such number. This mental action involves reviewing and reshaping earlier understanding in the context of the present problem situation (Pirie & Kieren, 1992). As well, the notion of story as a powerful vehicle in helping children examine and represent their mathematical understanding, as articulated by Borasi et al. (1990) was useful in describing and analyzing how the idea of story impacted how the children approached and developed their problem solutions or stories.

What follows is a detailed analysis of the videotaped session featuring the activity of the group of four students. The analysis includes a description of the children’s activity to provide the reader with a flavour of what was observed.

The notion of using story as a context for this task is strong for all the children and is evident in the way many of the students frame the task for themselves. In our mathematics’ classroom, books are frequently shared and discussed and the concept of story is used extensively when learning concepts. When reading books together, the children are invited to talk about the mathematical ideas they see embedded or emerging from the story. At other times, the children are asked to “tell the story behind numbers” and to write about what they are learning and have understood. As with other researchers such as Borasi et al. (1990) and Whitin and Whitin (2001), stories in books, personal stories and a variety of writing is valued in our classroom as a powerful way to learn mathematics and to represent one’s mathematical thinking

and understanding. As well, our pre-discussion shifted from using the word “question” to what “story task or story question” you could ask someone that would result in an answer of 25. The word “question” is confusing for most of the students. As indicated earlier, their experiences with problems has developed an expectation that problems are stories where all the information one needs to find a solution is present in the given story. Now they are asked to write such a story themselves where the only information is the solution. In this initial discussion, it is also clear that many of the children do not understand what is meant by a question. This is not surprising when I recalled all the instances when various children would launch into personal stories in response to a presenter’s invitation to ask her questions.

To set the stage, the children are asked to recall our discussion the previous day about the various ways that we could ask someone “to do something”, a story question, a story task or activity, that would result in an answer of 25. The students then are asked to consider 72 as an answer and are invited to select from a variety of manipulatives to help them create their question, task, story or activity either with their group members or on their own. They are also given paper to record their thinking so that all the children’s work could be examined later.

After carefully examining all the children’s recordings and sorting them into categories, it was clear that the small group’s activity could be used as a way to discuss how various children understand the number 72. What follows is a discussion of how each child (Noel, Elizabeth, Cole and James) understands 72 and use what he or she knows to create a story or a story game situation that represents 72 or has a goal of 72. The discussion will also suggest instances when individual children grow in their understanding through interactions with each other or with myself.

James and Cole both create similar stories about a store that sells items like cupcakes, muffins or cookies. They both use their selected manipulatives to initiate a story idea. At first, it looks like they are merely “playing.” The arrows that are constructed are unrelated to the stories they eventually develop on paper. As described by James, the arrows are merely “thinking arrows, they help me think.” But as they progress through the task, the materials seem to represent story elements rather than specific mathematical concepts and processes. It appears that James and Cole are engaging in a meaning making process where their understanding of number is being developed and represented as specific story elements (Borasi et al., 1990). The unifix cubes, tiles and dual coloured chips help them shape the story and the question that is posed at the end of their stories. As the two boys describe their stories, it is evident that their understanding of number is very different. In James’ story problem, he begins by describing a store that has 72 cupcakes to sell. James appears unable to conceive of 72 as being an answer. Perhaps due to previous experiences with typical story problems, he sees the need to include 72 in his story as part of the story question. In contrast, Cole’s story about a store includes concepts of money, multiplication, addition and subtraction as he describes how the shopkeeper sells various amounts of muffins and

cookies (ten cents each). Cole's story also describes how the shopkeeper suffers the theft of differing amounts of money at two different points in the story before he poses the question of "how much does the person have?" Cole has flexible, multifaceted images for the number 72 that he accesses mentally and represents as elements of his story. Through mapping (Pirie & Kieren, 1992) it is possible to draw a "map" of Cole's activity and to identify, track and analyze the growth of Cole's understanding with the aid of the Pirie-Kieren model (see Figure 4 for the pathway mapping Cole's growing understanding).

The videotaped recording gave me a way to analyze Cole's actions with the manipulatives, his conversation with group members and our discussion together, providing me with a way to trace his movement between the layers of the model. Cole is at a level in his mathematical understanding that the Pirie-Kieren model describes as image having. He no longer needs to perform certain actions with materials to demonstrate concepts such as addition, subtraction, multiplication or division. Rather, Cole can manipulate his mental images as if they were objects to compose his story. The previously described events are all image having activities. Cole has also crossed what the Pirie-Kieren model describes as

the "don't need boundary" between the image making level and the image having level. Cole's understanding of "the number 72" is not tied to a specific image. Rather he is able to flexibly and mentally create story details that require him to mentally calculate the total earnings from the sale of various amounts of muffins and cookies and to track the total earnings after losing various amounts of money through theft. Cole recognizes that 72 can be represented by groups of muffins and cookies, as differing amounts of money and as mathematical processes where 72 is the result. The Pirie-Kieren theory describes this level of understanding as property-noticing, a level where learners recognize properties of a concept such as "that 72 can be represented by multiplication or by the processes of adding and subtracting amounts of money." Unlike Cole, property noticing is absent in James' understanding. James prides himself on being able to quickly calculate equations. Numbers are for calculating. He does not seem to make the connection between calculating and the reason for calculating or in other words, the story behind the numbers.

Figure 4. A mapping of Cole's growing mathematical understanding.

James and Cole worked independently, there was virtually no discussion of their stories either between the boys or with myself. In contrast, manipulatives and prolonged discussions were central in how Elizabeth and Noel created their games. The game idea was a radical departure from the approach used by other children to weave a story around the number 72. This is a highly atypical context for exploring number for these children. There is no guiding information or story leading them to a correct answer. They have to imagine and write the story themselves. Creating games was the way Elizabeth and Noel respond to this challenge. These children used their manipulatives extensively to make and explain their individual games. Ongoing discussions with each other and with myself prompts both Elizabeth and Noel to engage in specific actions that results in the emergence of richer, personal understandings for number. Both children recognize that 72 can be broken down in a variety of ways but their progress is slowed by the need to “fold back” to examine, strengthen or create images for specific concepts such as multiplication and division. The number of players in Noel’s game changes progressively as his images for multiplication and division become more developed. The number 72 is initially represented in his game as the number of stops a player’s bus can make and the total number of passengers that get off the bus at the various stops. Each bus holds four people (the bus is eight multilinks snapped together with four bingo chips on top) and players race each other to see how many people they can “put off at the most stops.” These story elements represent Noel’s primitive knowing about the structure of games which he uses to build images for the number 72. After beginning to make rows of pennies (a penny represents one stop), Noel asks “what is half of 72?” He appears to be trying to create a game where two players try to race each other to see which one can get to their half of the stops first. Noel needs to fold back from image making activities to his primitive knowing that an even number can be broken into two groups. He then uses this for the number 72. My intervention is intended to help him make an image of how 72 can be divided into two groups, an intervention described by Pirie & Kieren as invocative. After placing dual coloured chips into ‘partners’ while counting by twos to 72, two rows are created with 36 chips in each row which I believe “shows” Noel that half of 72 is 36. However, it is not apparent to Noel as he continues to count all the chips then one row of chips and eventually the number of pennies in his rows to establish and re-establish the number he seeks. He folds back to primitive knowing about how to count objects to 72, one by one. Noel seems to be working at the image making level, trying to create an image that will help him to build the game but he returns to an earlier understanding of number to help him create the images he needs to create the game. As he continues to develop the game for four players then six players, our discussions center on the total number of stops in the game and the number of stops in each of the four then six “alleys.” I am trying to grasp his current level of understanding. While this is the intention of my validating intervention, I am not sure that Noel responds in the manner the intervention intends. At times, he would begin another

image making action such as counting or placing more pennies on rows or would simply wander off! By the time Noel scribes his directions to me for how the game is played, it is apparent that he has worked out how 72 can be developed into a game for two, four or six players.

The goal of Elizabeth's game is also 72 people being dropped off at stores but three people disembark at each store. Each player has a "train" of 10 connected multilink cubes with 10 coffee beans on top of each train. Coffee beans represent the people and dual coloured chips represent the stores, one row of red chips or "stores" and one row of yellow chips or "stores. Elizabeth attempts different ways to set up the game with the various materials using her primitive knowing about numbers. When we begin to talk about her game, she tells me she has "too much" because 40 and 40 is 80. She is referring to the two rows of 13 chips with 3 beans on each one and a single bean at the end of the row or  $13 \times 3 + 1 = 40$  plus  $13 \times 3 + 1 = 40$  for the two rows. Our conversation centers on having her explain what she is doing and thinking. Elizabeth has folded back to her image for the quantity 80 but this is not a useful image. Elizabeth very quickly says she needs to figure out "how many pairs of chips with three coffee beans on top would be 72." She needs a new richer image that will help her to continue designing the game. Without further conversation, Elizabeth continues to add chips to the rows until she has counted by three's to 72. She needs an opportunity or space to consider what she has done and is thinking about and how to proceed. In folding back, Elizabeth may have accessed images she has for number and developed richer images (image making) to guide her in completing the game.

This study suggests that primary children approach problem tasks with rich, diverse and flexible levels of mathematical understanding. In this study, the children were asked to use what they understand about number in a situation they had never encountered before. In previous experiences, problems had been solved by using the information in the story problem. Now they are asked to create the information or story where the answer would be 72. For some children like James the novel problem situation remained an obstacle preventing him from seeing the answer of 72 as separate from the story information. For other children like Cole, stories provide the means to represent their thinking and understanding. Composing a story provides children with a way to "generate and elaborate mathematical ideas" and to engage in problem posing in a manner that honours current thinking while encouraging a deeper understanding of mathematics (Borasi et al., 1990). The context of story helped children like Elizabeth and Noel to grow in their mathematical understanding of number. While weaving details of the game, these two children used current number knowledge and evolving knowledge to develop the games. At the same time, the story game context created a need for new images to guide the creating process. Teacher interventions play a key role in supporting the growth of the children's understanding by providing thinking space. The intention of teacher interventions is to provide children with opportunities for them to independently construct or modify their personal images. Often teacher

interventions are meant to verbally prompt children to return to their conceptual images, to create new richer images that will guide their outer actions. However such interventions can also create a space where the child is given a quiet place for reflection unhindered by time or conversation. An unusual task occasioned the creation of oral and written stories as the primary children grappled with how to create a problem task or question where the answer is 72. While writing their stories, some of these children also grew in their understanding. The stories of 72 authored by these young children reveal an understanding of number that is both diverse and complex.

### **...AND THE ANSWER IS 72: MATHEMATICAL UNDERSTANDING THROUGH OPEN ENDED TASKS**

Shelley Saltzman  
shelleys@interchange.ubc.ca

This poster focuses on children's mathematical understanding of basic operations in mathematics, such as addition, subtraction, multiplication as well as estimation and place value, when they are given an open-ended task.

The research involved the videotaping of an interview with a group of grade 4 students. This particular group is comprised of children, about whom their teacher has some concerns regarding their understanding and performance of mathematical skills. It is for this reason that these particular children became members of the focus group. The data was analysed through the use of the Pirie-Kieren Theory for the Dynamical Growth of Mathematical Understanding. (Pirie & Kieren, 1994).

The task posed was to make up a problem for which the answer is 72. The students were divided into two groups of three and were initially given about 15 minutes to come up with as many problems as they could. They were each given paper and a pencil, and had access to their textbooks.

It is worth noting that in the three months that I worked with, and observed this class, the students had no exposure to any sort of open-ended activities or problems. In addition, I never observed any group activity during math class. The students' sole direction in learning and understanding has been by way of a single dimensional approach to the learning of a particular algorithm. In the time that I was in the classroom with these students they did a short unit on estimation. The textbook presented the idea of estimation, for the most part, by a series of addition and subtraction exercises, whereby the students were asked to give, not an exact number, but rather an estimated one. The exercises were generally not situated within an appropriate everyday context.

It is clear that the mathematics used by the students in the new problem situation reflected their prior learning experiences. In general, the students did not come up with situational problems, but rather exercises in addition and subtraction and, in some

cases, multiplication. When asked to come up with their own problem, not one of the students entertained the idea of coming up with a problem involving the concept of estimation. When it was suggested that the students think about using their estimation skills in the creation of their problems, one girl said, "I can't do estimating." One of the boys said, "Estimation is just guessing." In this school year the students spent several weeks practising algorithms for addition and subtraction, and it is these algorithms and rules which form the pupils images for number operations. The poster will elaborate on the nature of images and explore how they were able, and unable, to use them in creating questions which led to an answer of 72.

### **IS IT AN ALGEBRA QUESTION? – ANALYSIS OF STUDENTS' STRATEGIES WHEN SOLVING A NUMBER THEORY PROBLEM**

Shevy Levy  
shevy@telestraining.com

The theoretical underpinnings of this study came from the Theory for the Dynamical Growth of Mathematical Understanding (Pirie, 1988; Pirie & Kieren, 1989, 1994). The Pirie-Kieren theory provides a way to visually trace the thinking actions of individuals working mathematically, and the growth of their mathematical understanding in a non-linear process related to *particular mathematical topics*. The theory posits *Primitive Knowing* as the inner layer of the model, which contains all a student's prior understandings that may influence the growth of the *new topic* being considered. In addition, it has been shown that when faced with a problem, students need to *fold back* to an inner layer of understanding, often their primitive knowing, to enable them to extend their current inadequate and incomplete understanding.

Several questions have arisen which form a focus for the paper: 1) How do students solve a non-routine mathematical problem? 2) What connections, if any, do students make to their primitive knowing when introduced to a new problem category? and 3) to what extent do students' existing understandings assist or hamper their growth of understanding of a new problem category. It is the purpose of the poster to discuss possible answers within the context of observing how students solve a particular number theory problem, a topic not included in school curricula. The problem was:

Alfie: Can you guess the ages of my three children? The product of their ages is 72.

Beatrice: That's not enough information. Give me another hint.

Alfie: My youngest child is more cheerful than my twins.

Beatrice: Now I can figure it out!

Six pairs of middle school to university level students were engaged for one-hour sessions in informal settings. The participants were asked to think aloud as they

worked and responded to a word problem. All sessions were videotaped and transcribed. The students were encouraged to use pencils and papers to record their work. The analytical model for examining the videotape data emerged from the research activity of Davis, Maher & Martino, (1992), Mercer (1995), Pirie (1996, 2001) and Powell (2001). Analysis of the transcripts focused on characterizing students' individual behaviour as well as identifying trends or similarities across their actions. Analysis of students' actions, inter-student discussions, and their written work were used to produce a description of the students' growth of understanding as they worked through the mathematical task. With the investigation of each individual, clearer patterns of students' mathematical growth of understandings emerged. Most students considered the problem "algebraic", and tried to solve the problem through a two-equation system. It was evident that existing understandings of algebra did not assist their growth of understanding of a new problem category. In my poster I will illustrate some of the students' errors and discuss possible answers to the research questions.

### **THE ANSWER IS THE QUESTION: THINKING BACKWARDS WITH EXPONENTS AND LOGS**

Amy Bamford  
amy\_bamford@hotmail.com

This poster investigates students' growth of understanding during an open-ended problem solving session. Through focusing on this topic review session involving senior level high school students, I investigated the different images held among students for exponents and logarithms. I also investigated the different ways in which students accessed these existing understandings as they were required by the problem solving situation. More specifically I considered the ways in which students recalled and used their existing understandings when faced with a novel problem solving opportunity.

The theoretical framework I employ is the Pirie-Kieren Theory for the Growth of Mathematical Understanding. (Pirie & Kieren, 1994) This theory provides a means of analysing the growth of understanding as students revisit their existing images of exponents and logarithms and try to apply these understandings in new situations.

The students involved in this research are grade 12 level mathematics students in an enriched class at a private Catholic high school in North Vancouver, BC. The students are capable and motivated mathematics students. The students are working on an open-ended problem solving opportunity as a review of a recently completed unit on exponents and logarithms. The unit included topics such as exponential functions, the laws of logarithms, mathematical modelling, geometric sequences, and logarithmic functions. Students are placed in small groups and are posed with the problem "The answer is 72. What is the question?" The students are further challenged to create "challenging" questions to puzzle their classmates and problems that review

each of the concepts in the unit. The mode of inquiry is video recording of classroom small group work in problem solving. Two digital video cameras were placed around the classroom, each one focusing on the discussion of one small group for the duration of the session. The video data was analysed to produce a meaningful picture of the growth of understanding of each small group of students as they worked on the problem.

The poster offers an analysis of this video footage by mapping the growth of understanding of each of the three groups through the levels of the Pirie-Kieren model. It also highlights the common features and the differences in the growth of student understanding for the different small groups. Particular attention is paid to the place of 'folding back' to prior understanding and to the working of students at the Property Noticing level of the theory.

### Notes

<sup>i</sup>This is a group of teachers, faculty members and graduate students from British Columbia, Canada who work regularly together and are undertaking and interested in research into the growth of mathematical understanding at all stages and levels of learning, from early childhood to the work place.

<sup>ii</sup>This research was supported by the Social Sciences and Humanities Research Council, Grant Number 410-1999-0159.

As part of a larger study investigating students learning dynamical systems, this report examines how one university student developed powerful ways of knowing acceleration with a tool called the water wheel. Our goal in this analysis is to better understand the use of tools and bodily activity in mathematical learning and how they suggest alternative characteristics to knowing. In particular, we develop the idea of “knowing-with” as it relates to the use of tools and bodily activity. In so doing, we contribute to a line of research that seeks to develop constructs and perspectives for inferring the quality of students’ mathematical experiences.

## **Introduction**

In this paper we elaborate on a particular type of knowing that Broudy (1977) called “knowing with.” He proposed that this form of knowing is different from two other types of knowing that are usually proposed: “knowing that” and “knowing how.” Knowing-that is declarative knowledge, the type that is typically expressed in verbal assertions and theory-like elaborations. Knowing-how is performative and gets expressed in actual performances. A typical example used to make the distinction is, say, that of the tennis player who masters certain types of serves by being able to do them (knowing-how) and the tennis analyst who describes what bodily abilities enables certain players to be good at those servings (knowing-that). The phrase “knowing with” means that there is something else that is a central part of knowing: the thing one uses or becomes familiar with<sup>2</sup>. An analogy might be the light that illuminates the page we are reading. As we read we are not consciously analyzing the light that makes the text visible for us. Nor is the ambient light a component of our knowing how to read. Similarly, someone who is or becomes fluent with a tool or a technique may illuminate with this fluency a way to look at a phenomenon, neither explicitly “applying” certain facts or theories about the tool or technique (which would be knowing-that), nor executing procedures that are part of its use (which would be knowing-how).

In reality all three forms of knowing play out together with more or less relative prevalence. For example, take the case of knowing a foreign language. Becoming a fluent speaker in a foreign language entails, in addition to knowing how (e.g., utter

correct expressions appropriate to the circumstances) and knowing that (e.g., stating grammatical rules), developing certain views and sensitivities regarding the things talked about. These views and sensitivities enable us to grasp humor, poetry, word games, and many other phenomena that are difficult or impossible to translate—they constitute what we would call knowing-with the foreign language.

We propose that knowing-with is an essential and not always recognized aspect of developing fluencies with tools and techniques in mathematics education. As an elaboration and refinement of what Nemirovsky, Tierney, and Wright (1998) refer to as “tool perspective,” knowing-with suggests an important alternative characterization to knowing, which may be useful for teachers and instructional designers interested in understanding more deeply the role of tools and bodily activity in mathematical learning.

### Theoretical Orientation

As a general orienting perspective, we draw on the theoretical orientation of symbolic interactionism as described by Blumer (1969). From this perspective meaning is neither located in a thing, like a water wheel or a graph, nor does meaning arise through a person’s psychological organization. Rather, meaning develops through and is located in interactions—interactions with others and self-interactions. Compatible with this perspective is Nemirovsky’s (1994) notion of symbol-use. Symbol-use, in contrast to symbol-system, refers to “the actual and concrete use of mathematical symbols by someone, for a purpose, and as part of a chain of meaningful events” (p. 390). We define symbols broadly to include conventional and unconventional inscriptions, physical objects, gestures, physical activity with a device, and utterances. Because gestures often co-occur with speech and because a speaker typically does not differentiate between the gestures she uses and the words she says (McNeil, 1992; Varela, Thompson & Rosch, 1991), we found this broad definition of symbol necessary in our attempts to make sense of the complicated process of construing meaning.

### The Study

We conducted a total of eight, 90- to 120-minute open-ended individual interviews with three students, Jake, Monica, and Kyle. Each student had completed three semesters of calculus and had taken or was taking differential equations. In the interviews students worked with a physical device called the water wheel (described below). All interviews were videotaped and transcribed. Summaries of each interview were developed and compared across all interviews. In this report we focus on an approximately 16-minute episode with Jake because it was most helpful in our understanding the role of tools and bodily activity and for framing the mathematical learning of the other two students. Just as in the case of the foreign language, Jake’s use of the water wheel entailed all forms of knowing; however, the episode we have selected allows us to trace with particular detail his knowing-with the water wheel.

As shown in Figure 1, the water wheel consists of a clear, circular acrylic disc holding 32 plastic tubes around its perimeter. The disc is mounted on an axle and is

free to rotate a full  $360^\circ$  and tilt between 0 and approximately  $45^\circ$ . In the middle of the disc are two concentric clear plastic cylinders that contain a variable amount of oil that acts as damping for the system. The amount of oil can be adjusted by raising or lowering the oil container shown on the right side of Figure 1.

*Figure 1. Water wheel.*

Blue colored water from a bucket with a submersible pump (with adjustable flow rate) showers into several contiguous tubes. When tilted, the tubes that receive water are on the “higher side” of the wheel. Each tube has a small hole at the bottom that allows water to drain out, which then collects in a drip pan and is directed back into the bucket containing the submersible pump for a continual flow of water into and out of the tubes. When the wheel is tilted and there is even a slight variation in the way water is distributed in the tubes, gravity causes the wheel to rotate. The rotation can be constant, periodic, or something more complicated depending on different parameter settings (tilt, pump flow rate, and oil level) and on the amount and location of water in the tubes. During periodic motion, water in the tubes tends to collect on one side of the wheel in a bell-shaped form. Students in our study referred to this as the “heavy spot.” Figure 1 shows this heavy spot near the bottom left of the wheel. In the next section of the paper Jake simulates the heavy spot with stacks of marbles that can be inserted into the tubes. When connected to a computer, optical sensors collect data with real-time displays of angular velocity versus time, angular acceleration versus time, and/or angular acceleration versus angular velocity. For a further description of this tool see Nemirovsky and Tinker (1993).

### **Discussion and Analysis**

#### **Revisiting Earlier Conclusions**

At the start of the second interview Jake revisited his conclusions from the first interview about the rotational motion of the water wheel depicted by three different velocity-time graphs (a constant positive velocity, a varying sinusoidal-like velocity graph in the first quadrant, and a varying sinusoidal-like velocity graph along the t-axis, all shown in Figure 2). For each velocity-time graph, Jake knew-how to simultaneously trace the graph with his left hand while enacting an imagined diagram of the wheel with his right hand. These rotational motions were constant, fast-slow, and back-and-forth, respectively). The snapshot shown in Figure 2 depicts Jake engaged in this process of being the wheel. Jake’s knowing-how to coordinate the water wheel motion and the velocity-time graphs was mediated by his knowing-that when the velocity-time graph crossed the t-axis the water wheel would reverse direction, that local maximums and minimums correspond to when the heavy spot is at the bottom of

the swing, and that the sign of the velocity indicated clockwise or counterclockwise motion.

An additional example of knowing-that is evident when Jake next revisited his development in the first interview of the acceleration versus velocity graphs corresponding to each of the three different velocity versus time graphs (see Figure 3). Jake recast the three velocity-time graphs as a point along the positive velocity axis, a circle centered along the positive velocity axis, and a circle centered at the origin. When creating his circle shaped graphs in the acceleration versus velocity plane, Jake capitalized on his knowing-that the acceleration is zero when the velocity is maximum or minimum and his knowing-that acceleration is positive when the velocity is increasing. Rather than being the wheel, it was through these calculus-based relationships that Jake recast the velocity-time graphs as acceleration-velocity graphs. Jake knew acceleration as a consequence of his knowing-that it is the derivative of velocity.

### Computer-Generated Graphs

As an entirely new activity, Jake next explored computer-generated graphs of acceleration versus velocity by physically moving the wheel with his hand. For the three types of motion (constant, fast-slow, and back-and-forth) he generated acceleration versus velocity graphs that were consistent with his expectations. For example, Jake said, "According to this [points to the board and traces out the circle centered on the positive velocity axis], if I speed up and slow it down, speed up and slow it down, it should be somewhat, kind of like a circle." After moving the wheel with his hand in a fast-slow, fast-slow manner (see Figure 4), he obtains a computer-generated graph that "seems to follow the general pattern." Jake goes through a similar process for the other two types of rotation and is satisfied with the overall consistency between his expectations and the computer-generated graphs.

Chris then offered Jake stacks of marbles taped together to simulate a "heavy spot." After inserting the marble stacks into three contiguous tubes, Jake continued his examination of computer-generated acceleration-velocity graphs for the case when the wheel moves back and forth without ever completing a full revolution. As Jake investigated the way in which the acceleration versus velocity curve

Figure 2. Velocity-time graphs.

Figure 3. Acceleration-velocity graphs

Figure 4. Computer-generated graphs.

evolved over time with the marble stacks, he knew that the wheel would eventually come to rest and expected to see the acceleration-velocity graph “wind down to zero.” Because the software only collects data for a set amount of time, this did not happen. Jake decided to adjust the starting position of the wheel so that the simulated heavy spot was relatively close to its resting position, and thus he could more or less observe the acceleration-velocity graph winding down to zero. This is part of developing a tool perspective (Nemirovsky, Tierney, & Wright, 1998) where a person figures out what is and is not a consequence of the tool.

### Finding an Apple

Jake’s tool perspective develops further in the next excerpt, where he ascertains whether an unexpected acceleration versus velocity curve is or is not an accidental byproduct of the marble stacks. Recall that Jake related the back-and-forth rotation to the circle centered at the origin in the acceleration-velocity plane.

- (1) Chris So, what if we, um, take our heavy spot and started further, like up here [close to the top of the wheel] [Jake: Oh, OK.] Just when it’s about to, ready?
- (2) Jake Yeah.
- (3) Chris Huh. Why do you sit back and fold your arms, Jake? [Laughs.]
- (4) Jake Well, I was thinking why the acceleration went down momentarily [points to two lowest places on graph in the third and fourth quadrants – see Figure 5]
- (5) Jake Ohhhh.
- (6) Chris So, it did something like [Chris draws an apple shape on the board similar to that in Figure 5]
- (7) Jake Yes, yes. Like, an apple. [Chris: Like an apple] Yeah.
- (8) Jake You know, I was wondering why I have, I, I mean, right now it seems like going pretty circle. But, especially like, like that, the initial, that initial, uh, run. Acceleration seem to, uh, or, or the, uh, acceleration,
- (9) Jake Let me think, this is positive acceleration [traces out counter clockwise motion over the wheel] and this is a negative acceleration [traces out clockwise motion over the wheel]. OK, um.
- (10) Jake So, initially, it went this way [with his left index finger he traces out the start of the curve in the first quadrant]. So, it was positive [his right hand traces out counterclockwise motion over the wheel]. It [acceleration] became negative somewhere around here [at the point where the wheel changes direction]. And, so this is the point when the, uh, velocity is zero and the acceleration is at the max., So, it must be at top

when, when the acceleration wasn't so big too much. And . . . huh [folds his arms and sits back].

This excerpt begins with Chris suggesting they start with the heavy spot closer to the top of the wheel (1). The resulting computer-generated acceleration versus velocity graph is a surprise to Jake because instead of a circle shape graph, which is what he expected, the initial portion looks like an "apple" (7). Jake is curious to figure out why the "acceleration went down momentarily" (4), where down refers to the two lowest places on the acceleration versus velocity curve. In Figure 5, Jake points to one of the "down" spots.

Figure 5. The apple shape.

Jake's use of the term "down" is a feature of the shape of the acceleration-velocity graph. Down does not appear to be related to the motion or rotation of the water wheel, either in terms of velocity or acceleration. The initial momentary down portions of the graph and the later graph that is "going pretty circle" (8) is a way for Jake to distinguish between what is unexpected and what is expected. Jake's attention to the differences in shape (circle versus apple) is significant because it gave him reason to pay attention to acceleration as it pertains to the actual motion of the wheel rather than derived from velocity.

As Jake enacts the motion of the wheel with his hand (9), he states that movement in one direction corresponds to positive acceleration and movement in the other direction corresponds to negative acceleration. Although Jake says acceleration, his conclusions are actually compatible with velocity (where counterclockwise is positive). The incorrectness of his statement about acceleration aside, Jake continues in (10) to coordinate his hand enactment of the motion of the wheel with both acceleration and velocity. In relation to different types of knowing, we see this as another example of Jake's knowing-how to produce motion according to certain graphs.

### Theory-Like Elaboration for the Apple

Jake then clears the screen and repeats the data collection, looking back and forth from the computer-generated graph to the water wheel and then staring intently at the wheel.

- (1) Jake Um. See, at the top, it was maximum acceleration. At the, at the, the, whenever, whenever it [the wheel] reaches the top, so, [Chris: OK.] at, whenever it swings down and reaches the top, it's, uh, maximum. It, at the maximum [gestures in a grabbing and pulling motion] acceleration, you know, this way [points and gestures in a counter clockwise direction]. Towards this direction [repeats gesture].

- (2) Chris OK, I'm listening.

- (3) Jake OK. Now. I think the reason why this went up [points to the dimpled part of the apple shape in the lower half plane on the computer-generated graph – see Figure 5] was because of the, uh, little momentum here. You know, I mean, when it came up, it went kind of, like this [jiggles a marble stack in one of the tubes], you know, because, you know, this thing was pulling down [gestures in a pulling motion]. But, the, uh, the thing was still trying to go that way. I mean, I, I can show you.

We characterize Jake's theory about the jiggling marble stacks accounting for the surprising apple shape as another example of knowing-that. Similar to when a tennis analyst carefully watches a player serve and theorizes why he continues to double fault (e.g., he keeps dropping his eyes), Jake is theorizing about something that he is noticing about the marble stacks. We think that this episode also illustrates Jake's knowing-with (illustrating again how different types of knowing often play out together).

We see two types of gestures in (1) that are particularly important – a grabbing and pulling gesture and a pointing and swirling gesture. In between the two words “maximum acceleration” Jake gestures in a grabbing and pulling motion followed by a pointing and swirling motion with his hand while he says, “You know, this way, towards this direction” and then repeats the pointing and swirling gesture. We see these two different gestures as important to Jake's knowing acceleration with the wheel. As Jake's grabbing and pulling motion followed by his pointing and swirling motion suggests, he is knowing acceleration with the water wheel because he is noticing the forces acting on the heavy spot, imagining what it is like for the marble stacks standing up in the tubes wanting to go one way while the wheel wants to go another way (3). These two gestures suggest a knowing-with the tool that is neither declarative nor performative.

### Knowing-With the Water Wheel

In an effort to support his marble-jiggling theory, Jake then leaves the room to get tissues to stuff in the tubes to prevent the marble stacks from shifting. Upon returning with paper towels, Jake wraps the marble stacks in the towels so that they fit snugly in

Figure 6. Acceleration-time graph.

the tubes. He generates a new acceleration-velocity curve and, much to his surprise, finds that the apple shape is still present, concluding that the apple shape is not the result of the marble stacks jiggling inside the tubes. At Chris's suggestion to try “some other graphs,” Jake decides to look at an acceleration-time graph and is as surprised at what he sees as he was when he saw the apple shape. It is likely that Jake expected to find a sinusoidal type graph, but instead found a graph with a “wicked move,” which he sketched on the board behind him (see Figure 6).

As the discussion surrounding the wicked move continued, Chris asks Jake, "Does it [the wicked move] happen when it's like this?" [setting the wheel in motion such that the back and forth oscillation is less than 180 degrees]. Chris's question at once refers to an unaccounted for aspect of acceleration and the spatial-temporal position of the water wheel. The phrase "when it's like this" merges both aspects of time ("when") with aspects of position ("like this") for the heavy spot. We see this as an example of fusion (Nemirovsky, Tierney, & Wright, 1998), where qualities of a graph are blended with actions that give rise to these qualities. Chris's question was not ambiguous or confusing to Jake as evidenced by the fact that Jake began moving the wheel with his hand to illustrate where he sees the maximum acceleration (at the top of the wheel's swing as before) and where he sees zero acceleration (at the bottom). Jake goes on to explain:

- (1) Jake OK. When it's up here [when the heavy spot is at the top of its swing], that's when the acceleration is the, uh, maximum. And, over here [bottom of the wheel], the acceleration is pretty much to zero.
- (2) Chris How do you know where the acceleration is maximum?
- (3) Jake Um. Well. One thing that I just noticed is that, uh. [Jake moves the wheel around so that the heavy spot is in different location] It seems to, uh, it, it seems to be proportional to the, well, see, as this thing goes up, it seems to . . . what? One, one thing I'm noticing [Jake carefully moves the heavy spot with his hand, feeling the force at different angles] is that, well, see, as I move this, I feel more weight right now, you know. But, the, uh, weight is almost zero up here [at the top]. Um. So, in other words, you know, up here [top], I don't have to apply, uh, as much force. As a matter of fact, it pretty much stays there. But, if it's in, you know, the middle. But, over here [heavy spot at the side], is, the force is like, the, uh, like a maximum. Um, um. And, uh, over, over here [bottom], of course, you know, the force is pretty much zero. So, uh, I don't know, force due to gravity, I think, it's, uh, like, like, almost zero. And, over here [side] it, it seems to be most, the force seems to be most strongest. . . . And, so, I think it has to do with the, um, the, uh, how do I say it? The, not, not the amplitude, well, maybe it's the amplitude. But, the, uh, angle of the oscillation. So, in other words, if I start, like, up around here [at the side], it should go, it shouldn't become like an apple shape. That's my theory. I mean, of course, I'll try it.

In (2), Chris asked Jake how he knew where acceleration is at its maximum. This question and Jake's response highlight how experience with a tool like the water wheel affords a certain way of knowing a mathematical idea like acceleration that is different from knowing-that acceleration is the slope of the tangent line or knowing-how to move the wheel in coordination with a velocity-time graph. When sensing and feeling the water wheel, Jake's way of knowing acceleration grew in him as he physically

moved the wheel with his hand. He says, “I feel more weight now” (3). By carefully attending to variations in the force he had to apply to keep the heavy spot in different positions, Jake distinguished when and why the wheel would experience a maximum acceleration. This excerpt exemplifies Jake’s knowing-with the tool. Much like how knowing-with a foreign language entails developing particular cultural subtleties and nuances enabling one to grasp humor or poetry, Jake’s knowing-with the water wheel enables him to develop certain views and sensitivities to force and angular position of the heavy spot that enable him to grasp acceleration. In this example, Jake neither explicitly applied Newton’s law of motion (which would be knowing-how) nor did he state rules governing the relationship between velocity and acceleration (which would be knowing-that). Rather, by being the wheel, where he imagines what it is like for the water wheel, Jake is knowing-with the water wheel.

### Concluding Remarks

As alluded to earlier in the paper, we see knowing-with as an elaboration and refinement of tool perspective. As described by Nemirovsky, Tierney, and Wright (1998), “Adopting a tool perspective involves emulating the tool’s sensitivity to certain aspects of motion and not to others, ascertaining conditions under which the tool is useful, and recognizing patterns of significance in the tool’s products” (p. 125). The tool perspective idea is a way to characterize how becoming fluent with a tool sensitizes one to aspects that are salient. Our analysis in this report helps to see the connection between this idea and forms of knowing that the idea of tool perspective does not finely distinguish.

We also highlighted in our analysis the important role of actually being the tool. In our different examples, being the tool was an important part of Jake’s developing views and sensitivities about motion, velocity, force, graphs, and acceleration. For example, when Jake was coordinating the motion of the wheel with the different velocity-time graphs, his gesturing with his right hand was a form of being the wheel as a means to tell the story of the actual motion of the wheel. In the theory-like elaboration for the apple example, Jake’s grabbing, pulling, and swirling pointing gestures was an integral part of his developing sensitivities to force, acceleration, and motion. In our last example, Jake’s touching and sensing the wheel—his being the wheel—were inseparable from his knowing acceleration with the tool. In these examples, being the tool is similar to how Ochs, Jacoby, and Gonzales (1994) describe how physicists create interpretive journeys through graphical representations, where they talk and gesture as if they are physically traveling through the inscription.

In this case study Jake anticipated that for back-and-forth rotational movement of the water wheel, the maximum acceleration would occur at the instant the wheel changed direction and that the corresponding shape of the acceleration versus velocity graph would be circular; but surprisingly learned otherwise. In the approximately 16-minute episode in which this story unfolds, our analysis highlights three different types of knowing: knowing-that, knowing-how, and knowing-with. As we illustrated

in our analysis, these different types of knowing are not disjoint and often play out together. Our analysis also underscores knowing-with as an essential aspect of developing fluencies with tools in mathematics education. Knowing-with a tool illuminates a way to look at a phenomenon, which is different than either carrying out procedures or applying particular facts or theories. Rather than a direct application of previously learned ideas and methods, knowing-with a tool like the water wheel is a process akin to organic growth that involves the whole body. Through his different gestures and physical interactions with the water wheel, Jake perceived and sensed forces and motion—imagining what acceleration is like for the water wheel. These developing fluencies are what enable him to grasp acceleration in ways that enrich and complement his knowing-that acceleration is the derivative of velocity and his knowing-how to coordinate different graphs with the motion of the wheel. Our work contributes to developing the knowing-with construct by adding a needed degree of specificity in relation to the use of tools and bodily activity in mathematical learning.

# COMPARING INSTRUCTIONAL STRATEGIES FOR INTEGRATING CONCEPTUAL AND PROCEDURAL KNOWLEDGE

Bethany Rittle-Johnson  
Carnegie Mellon University  
br2e@andrew.cmu.edu,

Kenneth R. Koedinger  
Carnegie Mellon University  
koedinger@cmu.edu

We compared alternative instructional strategies for integrating knowledge of decimal place value and regrouping concepts with procedures for adding and subtracting decimals. The first condition was based on recent research suggesting that conceptual and procedural knowledge develop in an iterative, hand over hand fashion. In this iterative condition, conceptual and procedural lessons were interleaved. The second condition followed the common ordering of conceptual lessons before procedural lesson (concepts-first condition). All lessons were presented via a computer-based intelligent tutoring system and seventy-two sixth-grade students participated. Students in the iterative condition made greater improvements in procedural knowledge and comparable improvements in conceptual knowledge, compared to the concepts-first condition. Students in both groups did better when problems were presented in money contexts rather than symbolically. Both the iterative ordering of lessons and presenting problems in money contexts reduced students' digit alignment errors when adding and subtracting decimals.

## Introduction

Competence in mathematics rests on children developing and linking their knowledge of concepts and procedures (Bisanz & LeFevre, 1992; Hiebert, 1986; Hiebert & Wearne, 1996; Silver, 1986; Sowder, 1992). However, competing theories have been proposed regarding the developmental relations and instructional importance of conceptual and procedural knowledge. Whether concepts or procedures develop first has been hotly debated within psychology (e.g., Gelman & Williams, 1998; Siegler, 1991; Siegler & Crowley, 1994; Sophian, 1997). Similarly, the "math wars" for how we should improve mathematics instruction have pitted conceptual understanding against procedural skill as the most important goal of mathematics instruction (Mathematically Correct, 2000; National Council of Teachers of Mathematics [NCTM], 2000). The mathematics education research community has begun to move beyond this dichotomy and recognize the importance of each type of knowledge. However, *how* conceptual and procedural knowledge are related is still not well understood. We propose that conceptual and procedural knowledge influence one another in mutually supportive ways and build in an iterative process. The purpose of this study is to compare instruction on decimals that is based on these mutually supportive, iterative relations to instruction based on the common sequence of concepts before procedures.

## Developing Conceptual and Procedural Knowledge

Recent research indicates that conceptual and procedural knowledge often develop in an iterative process, with improvements in one type of knowledge leading

to improvements in the other type of knowledge, which leads to further improvements in the first type of knowledge (Rittle-Johnson, Siegler & Alibali, 2001). For example, limited understanding of some domain concepts guides students' attention to important problem features and facilitates generation and use of a correct procedure. In turn, developing this procedural knowledge leads to improvements in conceptual understanding, perhaps by freeing cognitive resources for noticing patterns and relations, highlighting the importance of certain problem features, or revealing certain misconceptions.

Applying this iterative process to instruction could aid learning for several reasons. A "big idea" in reforming mathematics instruction is developing students' conceptual understanding of mathematics (NCTM, 2000). Although the general wisdom of developing students' conceptual understanding in a domain early in instruction is intuitive and an improvement over old practices, there are several reasons why iterating between conceptual and procedural instruction could lead to even greater learning.

First, presenting all the conceptual material first could overwhelm students' working memory and lead to confusion. Rather, some level of procedural fluency reduces working memory load (e.g., Shrager & Siegler, 1998) and could facilitate further improvements in conceptual knowledge. Second, iterating between conceptual and procedural lessons could help highlight the relevance of each lesson type for the other, avoiding the common problem of students not integrating conceptual and procedural instruction (e.g., Resnick & Omanson, 1987). Finally, iterating between varied, but related, tasks could support appropriate generalization of concepts and procedures, and thus reduce overgeneralizations (applying a concept or procedure in an inappropriate way) and undergeneralizations (failing to transfer to appropriate tasks) (Anderson, 1993).

Although this iterative instructional approach appears promising, past research does raise several cautions. First, conceptual understanding can be used to generate and choose good procedures (e.g., Geary, 1994; Gelman & Williams, 1998; Hiebert & Wearne, 1996), so it may be important to begin procedural instruction after students have firm conceptual understanding. Furthermore, some studies have found that prior procedural instruction can interfere with learning concepts (e.g., Warrington & Kamii, 1998). Thus, it is important to compare the effects of an iterative ordering of conceptual and procedural instruction to sequential ordering of conceptual instruction before procedural instruction (see Table 1).

### **Using Context to Elicit and Build Upon Informal Knowledge**

An additional big idea in mathematics instruction is eliciting students' prior, informal knowledge through real-world contexts (NCTM, 2000). Real-life story problems can be easier for students to solve than matched symbolic problems, partially because the context helps students avoid common errors (Carraher, Carraher, & Schliemann, 1985; Koedinger & Nathan, 2000; Rittle-Johnson & Koedinger, 2001). Nevertheless,

**Table 1.** Lesson Orders for the Two Conditions

| <i>Concepts-first condition</i>    | <i>Iterative (context-first) condition</i> |
|------------------------------------|--|
| 1. Contextualized concept lesson   | 1. Contextualized concept lesson           |
| 2. First abstract concept lesson   | 2. Contextualized procedure lesson         |
| 3. Second abstract concept lesson  | 3. First abstract concept lessons          |
| 4. Contextualized procedure lesson | 4. First abstract procedure lesson         |
| 5. First abstract procedure lesson | 5. Second abstract concept lesson          |

national assessments indicate that U.S. students do poorly on story problems and often do worse on story problems than on symbolic computation problems (Baranes, Perry, & Stigler, 1989; Lindquist, 1989). It is clear that not all story contexts elicit students' informal knowledge. Furthermore, there is little guidance for how to integrate context into conceptual and procedural instruction. Context could facilitate learning of particular types of knowledge. For example, context could facilitate links between conceptual and procedural knowledge because the grounded, informal context makes it easier to see the relations between the two types of knowledge. In this case, introducing procedural instruction in context immediately after conceptual instruction using the same context could facilitate links between the two types of knowledge. Context could also help students to bridge from grounded, informal concepts to abstract, mathematical concepts. This would suggest presenting instruction on formal mathematical concepts immediately after contextualized conceptual instruction. The two instructional conditions in this study contrast these two potential benefits of presenting problems in context (see Table 1).

In summary, we compared alternative instructional strategies for integrating knowledge of decimal place value and regrouping concepts and procedures for adding and subtracting decimals. We evaluated whether iterating between instruction on decimal concepts and procedures, initially within money contexts, led to greater learning than instruction that covered decimal concepts in context and in the abstract before lessons on decimal procedures. We also evaluated whether money contexts elicited informal knowledge and supported better performance on a decimal assessment. We predicted that iterating between lessons on decimal concepts and procedures would lead to greater learning and that providing money contexts would improve performance.

## Method

### Participants

The intervention was a component of a sixth-grade mathematics curriculum that we are developing. Four classes of sixth-grade students at our two pilot schools par-

anticipated. Each class period was assigned to one of the two conditions. Eighty-three students began this study and 72 completed the intervention and assessments, with an equal number of students in the two conditions.

### Intervention

The current study focuses on our computer-based intelligent tutoring systems for decimal concepts and procedures. The Cognitive Tutors provide on-demand, step-specific help at any point in the problem-solving process and immediate feedback on errors (Koedinger, Anderson, Hadley, & Mark, 1997). We designed three conceptual lessons on decimal place value and regrouping and three procedural lessons on adding and subtracting decimals.

In the conceptual lessons, students were asked to enter a number in a place value chart and then to show the value of the number in novel ways using regrouping (e.g., 6.0 as 6 ones, as 5 ones and 10 tenths, etc.; see Figure 1). In the first conceptual lesson, the problems were presented in a money context and using money terminology for the place values (e.g., dimes, pennies). On later conceptual lessons, the problem format was the same, but no context was given and symbolic place value names were used (e.g., tenths, hundredths).

In the procedural lesson, students were given word problems that required adding or subtracting two decimal numbers (see Figure 2). Students entered the numbers in a chart and completed the computations. In the first procedural lesson, problems were

**scenario**

You work as a bank teller and you need to give customers their money. Today, you only have hundred dollar bills, ten dollar bills, one dollar bills, dimes and pennies in your drawer.

Figure out 10 different ways that you can give customers their money. Finding a pattern will make it easier.

Jill wants \$5.10.

**worksheet**

|      | \$100   | \$10 | \$1 | \$0.10 | \$0.01 |
|------|---------|------|-----|--------|--------|
| Unit | hundred | ten  | one | dime   | penny  |
| 1    |         |      |     |        |        |
| 2    |         |      |     |        |        |
| 3    |         |      |     |        |        |
| 4    |         |      |     |        |        |
| 5    |         |      |     |        |        |
| 6    |         |      |     |        |        |

Figure 1. Screen shot of a problem in the contextualized conceptual lesson.

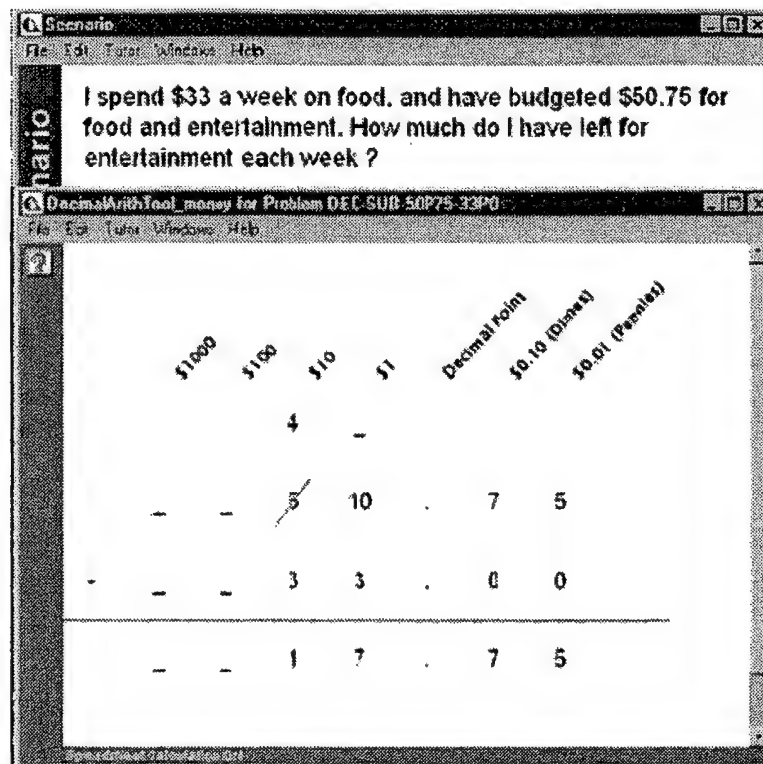

Figure 2. Screen shot of a problem in the contextualized procedural lesson.

presented in a money context, and monetary place value column labels were included on the chart. In the second lesson, problems were in non-money (often unfamiliar) contexts and the standard place value labels were included on the chart. In the third lesson, the chart did not include place value labels.

The order of these lessons varied by condition. Both orders began with the conceptual lesson on place value and regrouping in a money context. In the *concepts-first* condition, the other two conceptual lessons were presented next. Then, the three procedural lessons were presented, beginning with the lesson in context. In the *iterative* condition, the second lesson was the procedural lesson in a money context. Then, students completed the second conceptual lesson, followed by the second procedural lesson, and so forth (see Table 1).

Students worked on the Cognitive Tutor twice a week for four to eight weeks, with an average time of 4 hours and 10 minutes spent on the decimal lessons.

### Assessment

The pretest and posttest followed a 2 (Knowledge type: conceptual or procedural) x 2 (Context: money or none) x 2 (Learning type: learning or transfer) design, with 1 learning and 2 transfer problems in each of the other cells, for a total of 12 questions. See Table 2 for an example of each question type. We generated two versions of the

**Table 2.** Example Assessment Items

|               | Conceptual  |   | Procedural  |   |
|---------------|---|---|---|---|
|               | Learning  | Transfer                                | Learning  | Transfer  |
| Money Context | Show 5 different ways that you can give Ben \$4.07. | 2 dimes are worth how many pennies?     | You had \$8.72. Your grandmother gave you \$25 for your birthday. How much money do you have now? | You buy a super-size candy bar for \$1.12, a bag of chips for \$3.39 and a pack of soda for \$4. What is your total cost? |
| No Context    | List 5 different ways to show the amount 4.07       | 2 tenths are worth how many hundredths? | Add: $8.72 + 25$  | Add: $1.12 + 3.39 + 4$  |

assessment so that the same problem was presented in a money context and with no context (kind of “Difficulty Factors Assessment” see Koedinger & Nathan, submitted).

### Results

An alpha value of 0.05 was set as the criteria for all statistical analyses.

#### Pretest

We conducted a repeated-measures ANOVA on percent correct at pretest, with knowledge type, context and learning type as within-subject factors. Students solved more problems correctly when they were presented in a money context, rather than without context (63% vs. 31% correct),  $F(1,82) = 114.18$ . As shown in Figure 3, the benefits of context were greater on conceptual knowledge items than on procedural knowledge items,  $F(1,82) = 5.25$ . Comparisons of performance on individual items suggested that the money contexts reduced alignment errors when adding and subtracting (3% vs. 18% of relevant problems) and elicited knowledge of the relations between different place values, such as the number of pennies in a dime, on the conceptual items. Finally, students did better on the procedural knowledge items than on the conceptual knowledge items (59% vs. 44% correct),  $F(1, 82) = 9.96$ , and on the transfer items than the learning items (56% vs. 44% correct),  $F(1,82) = 13.44$ , though in both these comparisons other factors were not controlled and may account for the differences.

*Figure 3.* Effect of context on conceptual and procedural items at pretest.

### Effects of Condition on Learning

For each student, we calculated his or her gain score as the percent correct at post-test minus percent correct at pretest. To evaluate the effects of condition on learning, we conducted a repeated-measures ANOVA on the gain scores, with condition as a between-subject factor and knowledge type and learning type as within-subject factors. There was a main effect for condition,  $F(1, 72) = 3.92$ . As shown in Figure 2, students in the iterative condition made greater gains than students in the concepts-first condition (23 vs. 13 percentage point gain). There was also an interaction between condition and knowledge type,  $F(1, 72) = 4.91$ , such that the effect of condition was mostly on the procedural knowledge items. The effect of condition did not differ between the learning and transfer items. Comparisons of performance on individual items suggested that the iterative ordering was most beneficial on items where the “align numbers on the right” pre-conception seemed most difficult to override - when a two-digit whole number is added to a two-digit decimal number (e.g.  $8.72 + 25$ ). Students in the iterative condition made a 25% gain on this item, compared to no gain on this item in the concepts-first condition. Furthermore, students in the iterative condition only made alignment errors on 6% of relevant arithmetic problems at posttest, compared to 14% in the concepts-first condition.

Why did the iterative condition lead to better learning of decimal arithmetic procedures? Informal observations and quantitative data from the intervention suggested that the iterative ordering highlighted the links between the conceptual and procedural lessons. The conceptual task of representing a number in many different ways was novel to the students and very challenging. To solve a single conceptual problem

during the intervention, students spent 6 to 7 minutes, made an average of 6 errors and 1 or 2 help requests. The procedural task of adding and subtracting decimals was a familiar task for sixth graders and was much easier for them (2 to 3 minutes per problem, and less than 1 error and 1 help request per problem). Informal observations suggested that recognizing that ideas of borrowing from decimal subtraction could be applied to the conceptual task of representing a number in multiple ways facilitated understanding and performance on the conceptual task. If this was the case, students in the iterative condition should have done better on the later conceptual lessons, which were presented after a procedural lesson for these students (see Table 2). Although not a statistically reliable difference, students in the iterative condition outperformed students in the concepts-first condition on the second and third conceptual lessons. Students in the iterative condition took less time per problem (7 min vs. 8.2 min), made fewer errors (6.2 vs. 8.3 errors per problem) and asked for less help (2.1 vs. 2.7 help requests per problem) than students in the concepts-first condition (recall that during the intervention, students worked on a problem until it was correct). Students in the two conditions had similar performance on the second and third procedural lessons. Linking to students' knowledge of borrowing during the conceptual lesson may have strengthened this knowledge and helped to build connections between conceptual and procedural knowledge.

### Discussion

Both presenting decimal problems in money contexts and iterating between conceptual and procedural lessons on decimals led to greater success. First, these results contradict the common belief that word problems are harder than symbolic problems (Koedinger & Nathan, 2000). Students solved more problems correctly when they

Figure 4. Effect of condition on gain scores on the conceptual and procedural assessments.

were presented in money contexts, possibly because it tapped students' informal knowledge of needing to align digits of the same place value before adding and subtracting and of the relations between different place values for re-grouping.

Our findings also suggest that reform efforts to develop students' conceptual knowledge before their procedural knowledge need to be refined. Iterating between conceptual and procedural knowledge lessons, first in money contexts and later without money contexts, led to greater learning than presenting all the conceptual lessons first. This iterative sequencing was particularly beneficial for procedural knowledge. It seemed to help students avoid an over-generalization of the "align digits on the right" procedure that works with whole numbers. Introducing the procedural task early, and interleaving it with conceptual instruction, seemed to help link and strengthen knowledge shared by the conceptual task and the procedural task. These findings support an iterative model for the development of conceptual and procedural knowledge and help move beyond the debate on which type of knowledge develops first or is more important.

These findings also illustrate the interplay between research and practice. Theoretical constructs and laboratory research on the development of conceptual and procedural knowledge and on the effects of context guided the design of our classroom-based instructional intervention. This intervention led to improved student learning, and the classroom data provided empirical evidence to constrain theories on learning and teaching conceptual and procedural knowledge.

## **EXPLANATIONS OFFERED IN COMMUNITY: SOME IMPLICATIONS**

As the responsibility for providing explanations in the mathematics classroom shifts from the teacher to the students, a need arises for mathematics educators to better understand the implications of this transformed learning environment. Using a vignette and student work from a 7<sup>th</sup> grade mathematics class, we discuss some implications of creating learning opportunities based on student explanations. We note that explanations offered in this context can be understood as explanations in-action or explanations as re-presentations; that is, we make a distinction between explanations offered in the moments of meaning making and the explanations offered to others as a summary (or finished product) of one's own understanding. Further, we discuss how offering explanations is a relational activity and one that has ethical implications within a community.

The last two decades of research in mathematics education have demonstrated the value of nurturing students' mathematical thinking within mathematics classes that function as communities of learners (e.g., Cobb & Bauersfeld, 1995). However, such environments create challenges for the teachers as the responsibility for providing explanations shifts from the teacher to the students—or rather, to the teacher/students community as the teacher continues to play a distinct role in orchestrating the activities and the discourse in the classroom. Ball and Wilson (1996) offer a striking example of how encouraging and validating student solutions can leave the teacher in a difficult position when the students' responses are incorrect. "In considering curriculum, and in contemplating what it means to connect with students, teachers face a complex set of issues over what counts as worth knowing and what is entailed in respecting students as learners" (p. 186). In our work, we are interested in extending previous research to address and understand the conditions for and implications of creating a community of learners who engage in mathematical activity together.

In this paper, we turn our attention to student explanations offered in a classroom community. Through a vignette illustrating the events that arose in a 7<sup>th</sup> grade mathematics lesson we consider the manner in which explanations were offered and tease out some implications of creating learning opportunities based on student explanations. Specifically, we will address the features of the explanations offered in this context, the means by which they were accepted or rejected, and the possibilities for mathematics knowing that arose in offering and responding to explanations.

### **Theoretical Frame**

Our research is based on the premise that mathematics is a human activity of personal, social and cultural consequence; hence, mathematics and mathematics knowing

have ethical significance and implications. Such a premise is important for mathematics educators and learners—indeed for all who engage in mathematics—because it situates mathematics within our actions and interactions with other humans. Broadly speaking, the intent of our research program is to explore the ethics of mathematics knowing as it arises in teachers' and students' actions and interactions in the context of the mathematics classroom.

In our research, we heed Bateson's (1972) advice that we view ethics not as a question about whether the means justify the ends but as a question about the ecology of the act. "We have to find the value of a planned act implicit in and simultaneous with the act itself, not separate from it in the sense that the act would derive its value from reference to a future end or goal" (p. 160). Although a teacher may plan to deliberately do one thing and not another because of the potential consequences of those actions, ultimately, most of the teacher's actions and interactions are enacted in the moment (Mason, 1999; Varela, 1999). Therefore, the ethical implications of mathematics knowing are primarily situated in the moment. Our study fits within and draws on a body of research that attends to the mathematics knowing of children and demonstrates how understanding develops in a classroom community (Bauersfeld, 1988; Cobb, Yackel & Wood, 1992; Confrey, 1999; Yackel & Cobb, 1996). Like Ball and Wilson (1996), who are concerned with the relationship between teaching as a knowledge endeavor and teaching as a moral enterprise, and Lampert (1992) who is interested in the synthesis of effective and responsible teaching, we too are interested in studying the ethical features of teaching and learning mathematics. However, by focusing on the ethics of the moment by moment actions and interactions in the mathematics classroom our goals are to broaden our understanding of the ethical implications of teacher interventions, mathematics curricula, and mathematical explanations when offered in the classroom community. This paper is necessarily an incomplete contribution to this significant conversation of the mathematics education community. It is incomplete in that it is a response from a particular perspective and it is incomplete in that it generates new understandings and questions from which we can continue to explore.

### **Mathematical Explanations**

Our focus in this paper, in particular, arises out of our understanding of explanation as a relational phenomenon (Maturana, 1991). Mathematical explanations are a response 'to' someone *and* something. That is, the act of explanation is a response to an explicit or implicit question raised within the interactions among self-other-subject. The question arises, not from one of these sites, but in the 'dashes' or interactions in between. Explanations are also offerings 'for' someone, including ourselves, in an attempt to either provide an answer to the specific question posed or to broaden understanding of the topic of concern in that moment. Explanations are also responded to 'by' someone. The listener listens for the adequacy of the explanation according to some explicit and imposed or implicit and negotiated criteria. Underlying how mathematical explanations are offered and responded to are a set of assumptions, expecta-

tions and emotional responses. The explanations offered and the criteria by which they are assessed, establishes and continually reconstitutes what is viewed as acceptable mathematical practice and discourse in the classroom community.

Gordon Calvert (2001) distinguishes between two forms of explanations that occur in the context of mathematics classrooms: *Explanations in-action* and *explanations as re-presentation*. Explanations occurring in the course of mathematical activity are predominantly stated *in-action*. Explanations expressed in-action are offerings or invitations to oneself and others in an effort to broaden understanding in and for that moment. The explanations do not entail a search for an optimal expression and they are not evaluated against criteria of completeness or perceived correctness, but they are judged according to whether they are plausible, viable and consistent with previous experiences. Explanations stated in-action provide a layer of understanding in response to an immediate question or concern so the participants can continue on in their investigation. The explanation may raise new questions or may provide a means to further their investigation into a larger question. Explanations viewed as acceptable are incorporated into subsequent actions and are reexamined and revised when they no longer prove to be plausible. By interacting with the other through explanations in-action we make space for the other to exist beside us. We create the possibility for community.

Explanations as re-presentation are generally evoked when students are asked to summarize or re-present their explanations to other members of the learning community after a response has been formulated to a terminal question. The formulation involves a search for an optimal expression that encapsulates their activity and purposefully removes known errors and tangential activities. Upon presentation, the listeners' criteria for acceptance shifts from its usefulness for further activity to its perceived correctness and completeness to the question initially posed. Such explanations provide a mechanism for sharing the disparate activities in a classroom and potentially give rise to further questions. Explanations as re-presentations generally are offered within established communities—communities in which criteria for acceptance of the explanation are shared within that community, however loosely or well defined. In the case of mathematics classrooms the explanations offered by students and teachers have particular features that are observed to be mathematical. It is also the case that differing explanations and disagreements may provide opportunities for the community to broaden its understanding as a whole and to 'correct' inconsistencies between offerings of its members.

Returning to the implications and ethics of the situation, we note that whether the explanation is evaluated against criteria of viability and usefulness or correctness and completeness, it is immaterial without the response of the listener. If the listener accepts the explanation of the other then he or she accepts the other as a member of the community in which the explanation is offered. This leads us to ask: What does it mean to accept, reject or disregard the explanation of the other? What are the implications of such responses?

### Methodology

Our research program is dependent on the intersection of three research studies, each led by a different researcher, which focus on the interactions among teachers, learners and curricula in mathematics classes. Each of the researchers brings a particular interest to the projects at the same time as being interested in the questions of the other two researchers. We collaborate because we have found it fruitful to cross our research questions and interpretations with the others. Out of this blend comes new interpretations; ones we may not have come to if each of us were focused by the same research question or restricted to a common research site. In our research we interpret student actions and interactions in mathematics classes where students have been invited to offer explanations and listen to the explanations of others; we interpret teacher responses and responsivity in an effort to study teacher responsibility; and we interpret the curriculum that is brought forth in the lived experiences of the mathematics classroom.

In the site from which the data referred to in this paper are taken the researcher/teacher has conducted a year-long teaching experiment in which notions from complexity theory have been transformed and are being used to inform instruction (see Davis and Simmt, this volume). In this study the researcher/teacher takes responsibility for preparing for instruction, teaching the lessons and assessing student understanding. Data collected from these activities are transformed through transcribing audio and videotapes, scanning selected pieces of students' working papers and isolating specific video clips. A key feature of the data selection, transformation and analysis is that at least part of it is done in collaborative sessions where the research teams from each site work together on questions associated with their individual interests, the interests of the others and the questions and meanings that arise in the interactions among the researchers.

### Explanations for Teaching/Explanations for Meaning Making

In this section we offer a vignette and some students' work to illustrate how explanations were used for teaching and for meaning making. The vignette has been created from the data compiled during a 50 minute 7<sup>th</sup> grade lesson which was part of a unit on integer concepts and operations. The students' comments and displays illustrate the range of responses students offered to the class in the large group discussion. During that large group discussion a number of conceptions of integer multiplication were offered and developed. Student work shown in figures 1 and 7 illustrate multiplication as  $x$  groups of  $y$  integer disks; figures 2 and 8 suggest an understanding of multiplication as repeated addition/subtraction; figure 3 represents integer multiplication as hops on a number line; figure 4 illustrates a variety of connections within the topic; figure 5 demonstrates a procedural approach to multiplication; and figure 6 is a statement of rules for multiplication.

**Vignette**

The students working in pairs were given the task to find the result of  $3 \times -4$  and were directed to "show how you know." Immediately after the students paired off they began working. The researcher/teacher walked around the room and passed out double-sided disks to those who requested them. Many of the students took out their personal number lines. Earlier in the year the students had considered multiplication of whole numbers as repeated addition and they had just completed a study of integer addition. It was assumed that the students likely had considered multiplication as  $x$  groups of  $y$  objects in their elementary school mathematics. Prior to this lesson the students had not done any integer multiplication in this class. However, it is obvious that a couple of the students had been introduced to it before. The students worked for about 20 minutes developing their explanation (in-action). Then each pair of students prepared a display on a large sheet of paper which was subsequently put up on the bulletin board. As is frequently the case in the class, there were a variety of explanations offered by the students.

"Tara, tell me what you did here," the teacher asked as she pointed to Tara's display (figure 1).

"Well,  $3 \times -4 = -12$ , because the three groups of negative four chips equals -12 chips."

"Is there anyone else who has an explanation like Tara's?"

Cathy responded, "Ours is. We have three groups of -4 that makes -12" (not shown).

Another student added, "We have  $-4 + -4 + -4$ . That equals -12" (figure 2).

"That's a little differently said," the teacher suggested. "Isn't it Karen?"

"Well, it's really the same," Karen replied.

"We just didn't draw the chips."

"Actually, ours is the same. We drew the four groups, but we explained it more," commented Tim (not shown)..

"Who did this one?" the teacher asked as she pointed to another display which appeared to use repeated addition (figure 3).

"That's ours," Michael said.

Figure 1.  $x$  groups of  $y$  integer disks.

Figure 2. Repeated addition/subtraction.

"Why is there a zero?"

"He said we needed it," Michael said as he pointed to Aaron.

"Well, you need to start somewhere," Aaron explained. Aaron and his partner used a number line in their explanation. "That's ours over there" (figure 4).

"Oh, I see what you mean. On the number line you start at zero," the teacher said. At the far side of the room, one student's hand slowly went up. "Yes, Tim?"

"Actually, it doesn't matter where you start," Tim said slowly as though he was thinking through his idea.

"What do you mean?"

"No matter where you start, negative four three times is always negative twelve," he asserted. "Even if you start somewhere else on the number line" suggesting a vector interpretation. Tim's idea did not get picked up by any of the students in the class but it certainly did add to the possibilities that had been offered.

"What else have we got here?" the teacher asked looking around the room at the posters. "This one is interesting" (figure 5). Katie and Kelsey's poster offered a very "teacherly" display of their thinking with all parts of the poster neatly labeled and a few connections made to language and ideas they had studied before.

"That's ours," said Katie.

"We did it two ways," Les explained (figure 6). "First we did it with our calculator and then we did it like them."

As the class time was coming to an end, the teacher scanned the posters hang-

Figure 3. Repeated addition connected to number line.

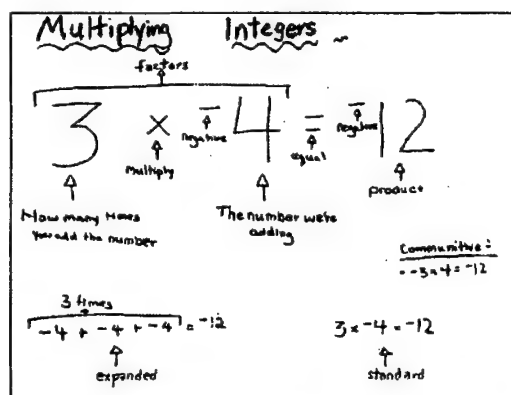

Figure 5. A variety of connections.

Answer: -12

$+3x - 4 = -12$

Ways to find  $12 \div 4 = 3$

1) Did it on a calculator:  $3 \times 4 = 12$

2) SAT: Three sets of -4:  $-4 + -4 + -4 = -12$

Figure 6. A procedural approach.

|                                       |              |
|---------------------------------------|--------------|
| POSITIVE                              | NEGATIVE     |
| <del>×</del>                          | <del>×</del> |
| POSITIVE                              | NEGATIVE     |
| <del>=</del>                          | <del>=</del> |
| POSITIVE                              | POSITIVE     |
| POSITIVE $\times$ NEGATIVE = NEGATIVE |              |

⊖ ⊖ ⊖ ⊖

Figure 8. Offered as different from the others.

ing that had not yet been discussed. "Here is another one that is different" (figure 7).

"That's ours," Jessica replied. "I learnt that last year. We wrote the equations on the back," Jessica added as though this helped with the explanation.

Wrapping things up the teacher said, "Well, it looks like the ones remaining are like the ones we have already discussed."

"No, ours is different," Samantha interjected (figure 8).

"Which one is yours?"

Samantha pointed to a poster that showed three groups of four negative disks.

"How is yours different?"

"Well, three times negative four is negative twelve because three times four is twelve and then it is negative because the 4 is bigger," she replied quite confidently.

The teacher hesitated, "Oh, it is? Tell me. What would four times negative three equal?"

After a brief moment Samantha responded, "Positive twelve."

A rumble started. Many of the students started speaking at once.

"No, it's negative twelve."

"It's commutative."

"It's still negative."

What a way to end the class!!

"Jared. You have been asking what's for homework. Here is your homework. I want to know what  $3 \times -4$  equals and what  $4 \times -3$  equals and you must be able to explain your response. We'll continue on from here tomorrow."

### Interpretations

While there are many interesting perspectives to take on the explanations offered, we address the following aspects in our interpretations of the students' displays and comments: features of the explanations; possibilities that arose in the offering; and responses to the explanations.

#### Features of Explanations

The students' displays could be described as explanations as re-presentations. That is, in the sharing activity described above, the students' activities and discussions in their small groups were re-created on chart paper as a response to the question posed. The explanations were created as "finished products" for discussion. While there was a possibility that the explanations provided might not be communicated clearly or thoroughly or that they might spark new ideas, there was no expectation, as they were being created, that the students would need to return to the explanations to work on them further.

From the few examples offered in figures 1 - 8, it can be seen how carefully the students created the displays of their explanations. These displays were neat and orderly; they provided illustrations and, in many cases, text to elaborate their points. These explanations served the immediate purpose of sharing ones thinking about a particular concept to people who were not privy to the original discussions in which the explanations were formulated. It is evident that the students knew that for an outsider to understand their explanations they would need to create an explanation that was both coherent and illustrative. Hence, simply the teacher's demand for a public explanation had consequences for the mathematical knowing that emerged.

The students' displays were also created in anticipation of listeners who held both explicit and implicit criteria for acceptance. In this particular classroom culture the students are aware that their displays are to intentionally communicate what they know. Most groups appeared to respond in similar ways to the explicit "show how you know" criteria. That is, they needed to not only answer the question "what is  $3 \times -4$ ?" but they had to respond to the more implicit concern, "the answer is (in this case)  $-12$  because ..." by drawing on their previous experiences in this and in other mathematical communities. We see that students responded by using their prior understanding of number and operations, their recollection of procedures and rules, and by using available tools (e.g., calculator and number lines). Further, it is interesting to note that in figure 5 the students who created that display also appeared to respond to a more general concern, "Show *what* you know about multiplying integers" by labeling symbols and providing definitions.

#### Possibilities that Arose in the Offering

The linking of explanations by way of same, similar or different conceptual principles provided important dimensions to the possibilities for learning and possibilities

for the culture of the learning community. Although these were explanations as representations, they also served the purpose of meaning making at the collective level. The mathematics community itself was brought forth in those acts of explaining and listening. It was our observation that one of the implications of offering mathematical explanations in class was that mathematical concepts (e.g., integer multiplication) and a mathematics community co-emerged in the interactions. Like Maturana (1988), we note that community is formed as participants come to share criteria for accepting explanations. In other words, we observed workings of the criteria of acceptance in the classroom community and the ways in which the implicit criteria for accepting explanations were negotiated and articulated by the community in the process of sharing.

### **Responses to an Explanation**

As illustrated in the vignette, the students were able to comment on their explanations and the explanations of others, as one by one their posters were the focus of attention. Students were eager to explain their displays to the others and most students in the class respectfully listened to the explainers. As students heard the explanations of others, a number of them commented that their explanation was similar: "Mine is like that." "You've already done one like mine". In other cases, students noted that their explanations (although they looked the same to the teacher and other students) were different to the others that had already been described. For example, two posters had three groups of four red disks (representing negative) with the mathematical equation  $3 \times -4 = -12$  written across the top of the sheet (figures 1 and 8). But after hearing the explanation of how the picture showed the result was -12, one student, Samantha, suggested that her poster (figure 8) was different than the one that looked very similar (figure 1). When asked how it differed Samantha responded, "Ours is -12 because the 4 is negative and it is bigger." Surprised by her explanation, the teacher asked, "What would  $4 \times -3$  equal?" The student quickly responded, "Positive 12." This immediately caused a reaction among the members of the class, as more than one student insisted that this would be -12 as well. A few even tried to explain with the model they had offered. Unfortunately, this response came very late in the class and the student objections ended with the dismissal bell. The students were packing up as the researcher/teacher asked them to think about the products  $4 \times -3$  and  $3 \times -4$  and to be prepared to explain "how they know".

In another case, a student took up the explanation of an other and extended it far beyond anything that had been discussed up to that point (and beyond what the teacher had thought about in her planning—see Davis and Simmt, in this volume). In that case, Tim, after hearing Michael and Aaron's discussion about why a zero was included in Michael's equation (see figure 3) argued that it did not matter where to start,  $3 \times -4$  is always -12.

Ignoring or paying little attention to a particular explanation is also a response. Notice how the teacher did not pay much attention to the "rules" for multiplying inte-

gers. The teacher deliberately passed over this poster a number of times and it was not until late in the class when the students interjected with it that it was introduced to the class discussion. In the case of figure 6, where the students carefully noted the keystrokes they used on their calculator and then offered repeated addition as a second way of showing how they know, the students boasted that they did it two ways. An intervention the teacher made when the students were working in pairs may have triggered them to emphasize that they did it two ways. When the teacher was circulating among the students as they worked, she noted that the students had written the keystroke sequence for the calculator. At that point she indicated to the boys that although this method provided a way of finding the product it did not illustrate an explanation of why  $3 \times -4 = -12$ . The students then added the repeated addition illustration. What implicit criteria of acceptance are being created by such actions? The criteria of acceptance are constantly evolving within the classroom community as teachers and students alike offer possible explanations, remain silent about some and challenge yet others.

### Conclusions

The act of explaining and offering an explanation is central in the mathematics classroom. As instructional practices move from ones in which teachers take responsibility for explaining, to instructional practices where the full classroom community is responsible for explanations, mathematics educators will need ways to think about these new environments. In this paper we have offered illustrations of possibilities as well as language to talk about the features of explanations; illustrated possibilities that arose from students preparing and sharing explanations, and responding to explanations within the classroom.

Our research suggests that the explanation is one feature of a mathematics class that is fostered by and fosters mathematical communities because it puts people in relationship with one another through their ideas. Explaining and listening in a mathematics class brings forth the community through the development of relationships that arise through making space for the other, and it brings forth a world of mathematics within which the particular group exists, as criteria for acceptance of a mathematical explanation emerge in action. In these ways, we claim the acts of explaining and listening and the resultant artifact—the explanation—are critical to mathematics education. However, once we begin to think about explanations in this way we find ourselves immersed in questions of ethics as we explore how students through their mathematical actions make space in their worlds for others (Varela, 1999). In other words, we suggest that offering an explanation in a grade 7 mathematics class is an ethical act because as Maturana and Varela (1992) note “every act in language brings forth a world created with others in the act of coexistence which gives rise to what is human. Thus every human act has an ethical meaning because it is an act of constitution of the human world (p. 247).”

## FOCUSING ON KEY DEVELOPMENTAL UNDERSTANDINGS IN MATHEMATICS

Martin A. Simon  
Penn State University  
msimon@psu.edu

Although mathematics educators uniformly are in favor of teaching for understanding, what is meant by “understanding” varies greatly. In this paper, I elaborate the construct of “key developmental understandings,” understandings that distinguish among levels of development of a concept. The construct does not represent an area of inquiry that is new to mathematics education. Rather it offers an abstraction of productive activity that has gone on in particular research projects on particular mathematical topics. With this abstraction, we can examine current research, curricula, and teaching. Using a classroom example involving fractions, I illustrate how focusing on key developmental understandings leads to a particular, potentially useful type of thinking and direction for inquiry.

- **Teaching.** Effective mathematics teaching requires understanding what students know and need to learn and then challenging and supporting them to learn it well.
- **Learning.** Students must learn mathematics with understanding, actively building new knowledge from experience and prior knowledge. (National Council of Teachers of Mathematics, 2000, p. 11)

Recent discourse in mathematics education has coalesced around the importance of focusing on and fostering students’ mathematical understanding. This agreement among mathematics educators has led to a commitment to generate new learning goals for students that are less skewed in favor of skill and facts learning, less focused on what students do and more on how they think. Thompson and Saldanha (in press) asserted that, “conditions for improved instruction entail an enduring discussion of what the community intends students learn” (draft p. 33). As part of this discourse, I introduce the notion of *key developmental understandings* as a way to think about understandings that can be useful goals of mathematics instruction.

The vast majority of mathematics educators would likely report that they endeavor to promote mathematical understanding. However, what they mean by “understanding” varies greatly (Sierpiska, 1994). The word is used so broadly that in mathematics education that it is of little value without further explanation. One of the most common uses of *understanding* is “knowing why something is true or appropriate” (e.g., why the denominator “remains the same” when we add two fractions that have like denominators). Certainly, we want mathematics students to have such knowledge. However, “knowing why” although characteristic of someone who understands, does not specify the important issues in developing understanding, and thus, is inadequate for specifying the goals of instruction. A second common perspective on

understanding is characterized by Hiebert and Lefevre's (1986) definition of *conceptual knowledge*: "knowledge that is rich in relationships. . . . a network in which the linking relationships are as prominent as the discrete pieces of information" (pp. 3-4). Although this is descriptive of understanding, it offers little guidance for determining useful goals for student learning.

In the next section, I use an example involving fractions to distinguish and elaborate the construct of *key developmental understandings*. My choice to coin a new term is based on my conclusion that "understanding" is likely to remain a term that lacks specificity and is therefore of little value in a scientific discourse. It is important to note that characterizing learners in terms of their understandings, it is not a claim that these understandings *exist* in the learner. Rather, it is a way that an observer (researcher, teacher) can impose a coherent and potentially useful organization on her experience of the learner's actions (including verbalizations).

### **An Understanding of Fraction**

I have often engaged teachers in thinking about what it means to have an understanding of fractions. Typically they respond that it means knowing that a fraction,  $m/n$  (my language), means that a whole is divided into  $n$  equal parts and that we have  $m$  of those parts. Consider this description in light of the following classroom episode.

In a fourth-grade class, I asked the students to use a blue rubber band on their geoboards to make a square of a designated size, and then to put a red rubber band around one half of the square. Most of the students divided the square into two congruent rectangles. However, Mary, cut the square on the diagonal, making two congruent right triangles. The students were unanimous in asserting that both fit with my request that they show halves of the square. Further, they were able to justify that assertion.

I then asked the question, "Is Joe's half larger; is Mary's half larger, or are they the same size?" Approximately a third of the class chose each option. In the subsequent discussion, students defended their answers. However, few students changed their answers as a result of the arguments offered.

I will offer an interpretation of these observations and then use this fraction example to ground the discussion of key developmental understandings. The students that argued that either the rectangular or the triangular half was larger conceive of halves as an *arrangement* in which a whole is partitioned into two congruent parts. They do not understand that partitioning a whole into two equal parts creates a new unit whose size, relative to the original unit (whole), is determined. That is, they do not understand that "one half" indicates a *quantity* (amount), not just an arrangement. Thompson & Saldanha, (in press) describe this limited view of fractions as an additive rather than a multiplicative relationship.

Educators, who understand a fraction as a quantity, find it difficult to think about this limited conception of one half (as an arrangement). I offer the following way of thinking about this limited conception. One can partition a square into two rectangles

with any cut parallel to one of the sides. Any such partition will create two parts that can be compared to each other and which sum to the whole. However, in the case where the partition results in equal parts, an important part-whole relationship is determined (from the perspective of those who understand it) – a new, specified unit of quantity is constituted. This special relationship between the part and the whole, created by equal partitioning, is neither obvious nor automatic to the young learner who is just beginning to explore fractions. It is an example of a *key developmental understanding*.

### **What is a Key Developmental Understanding?**

I use the above example of fraction understandings to point to two characteristics of key developmental understandings.

A first characteristic is that key developmental understandings involve a conceptual advance on the part of the learner. By conceptual advance, I mean a change in the learner's ability to think about and/or perceive particular mathematical relationships. In the fraction example, understanding that equal partitioning creates specific units of quantity represents a significant advance allowing the learner to conceive of and act with fractions in more powerful ways. Those who had this key understanding found the question of which half is bigger to be trivial. For those who did not have this key understanding, not only could they not see that the two differently shaped halves were necessarily equal, they could not follow the reasoning of those who could.

This last observation leads to a second characteristic: An indication that a key developmental understanding is involved is that those students without the knowledge do not tend to acquire it as the result of an explanation and/or demonstration. A key understanding is an important developmental step, one that is essential to recognize as a goal of instruction.

### **How Does One Identify a Key Developmental Understanding?**

Mathematics educators often cannot identify key mathematical understandings by examining their own mathematical understandings. What were key developmental issues early on in the development of their understandings are not apparent as they examine their now sophisticated understandings. Indeed, many key understandings develop without the learner's awareness that a conceptual advance has taken place. In the fraction example, I indicated that frequently educators consider one half to be one of two equal parts of a whole. Whereas this is a reasonable way to describe one's idea of one half, it is virtually useless in guiding instruction towards a concept of a fraction. The young learner can easily learn that the parts must be equal (usually assimilated as "identical" and based on their notion of fair sharing) and because they have whole number concepts, they can learn the correspondence between the whole numbers and the parts involved. Thus, it is relatively unproblematic for learners to identify a typical shaded rectangle with particular vocabulary ("one half") and symbols (" $\frac{1}{2}$ "). None of this represents a transition from thinking about whole numbers to thinking about fractions.

The most reliable way to identify key developmental understandings is to observe learners engaged in mathematical tasks in order to specify understandings that can *account for differences in the actions used by different learners to perform the same task*. In the fraction example, contrasting the learners who claimed that the triangular half was larger with the learners who claimed that the triangular half was equal to the rectangular half creates a context for identifying a key aspect of understanding fractions. This was in fact the strategy of Piaget (c.f., 1952) and his colleagues.

To summarize: a key mathematical understanding is a conceptual advance that is important to the development of a concept. It identifies a qualitative shift in the learner's ability to think about and/or perceive particular mathematical relationships, that is a change in the assimilatory structures that the learner has available. The emphasis here is on "ability to think about and/or perceive." I am not referring to a missing piece of information that affects one's performance. Rather, I emphasize that without engaging in a developmental process, the learner lacks a particular mathematical ability. The set of key developmental understandings specified for a concept is different than the taken-as-shared knowledge that the mathematical community has about the concept. Although there may be some overlap, these sets are often quite distinct. For example the formal definition of a rational number is quite different from the understanding of a fraction as a quantity discussed earlier.

One additional point is important to emphasize. Key developmental understandings can be specified at different levels of detail. If we return to the example of fraction-as-an-arrangement and fraction-as-a-quantity, we can compare that specification to the more detailed work of Steffe (2002) and Tzur (1999). The level of detail specified for a key understanding is adequate if it serves to guide the effort for which it is needed (e.g., teaching, curriculum, further research).

### **Key Developmental Understandings and Prior Work in Mathematics Education**

Significant work has been done in particular areas of mathematics education that could be characterized as research on key developmental understandings. Piaget (c.f. 1952) and Steffe (cf. Steffe, Cobb, & von Glasersfeld, 1988) have both directed major research programs of this type. Other examples include Thompson (1994), Tzur (1999), Heinz (2000), Simon and Blume (1994), Confrey (1994), and Behr, Harel, Post, and Lesh (1994). Thus, my postulation of the construct, key developmental understandings, is aimed at articulating a distinction that can be observed among existing examples. Although these examples exist and are valuable parts of the mathematics education literature, such research is still not widespread. Further, attention to key developmental understandings is generally not the basis on which curricula are developed. My elaborating this construct has three related purposes:

1. As mentioned in the introduction, the mathematics education community has used the term *understanding* in a nebulous fashion, and therefore the term has lacked specificity and power.

2. By abstracting from existing examples and naming the construct of *key developmental understandings*, I wish to call attention to a powerful basis for mathematics instruction.
3. By elaborating this construct, I aim to promote explicit discussion of and increased inquiry into key developmental understandings and their role in mathematics instruction.

Although some of the research done in the last 25 years has contributed to our knowledge of key developmental understandings, much more work of this type is still needed.

### **The Role of Key Developmental Understandings in Mathematics Education**

Understanding mathematical development involves having a sense of developmental steps and understanding how learners can progress from one step to another. Identifying key mathematical understandings is a way of specifying developmental steps. As key understandings are specified, inquiry into how these understandings develop and how they can be fostered becomes possible. Research is needed that can identify key understandings and describe developmental processes for many mathematical concepts.

A focus on key developmental understandings represents a significant change from a more conventional focus on students' knowledge. The former engenders a different set of questions for inquiry and a different direction for assessment and instruction. I use the fraction example again to illustrate this point.

If a mathematics educator identifies understanding of one-fourth as knowing that it is one of four equal parts that make up a whole, what kind of assessment might she generate? One possibility is that she creates a series of diagrams for which the students must decide if each represents one-fourth. Some of the diagrams would have one of four congruent parts shaded. Some would have more than one of the four congruent parts shaded. Some would have a different number of congruent parts and some would have unequal parts. (The reader is probably familiar with such assessments.) This assessment is appropriate for the specification of one-fourth as "one of four equal parts of a whole." That is, the assessment provides evidence of whether the student

Figure 1

knows that four parts are involved, that they must be equal, and that we are attending to one of those parts. However, if one begins with an articulation of fraction-as-a-quantity as a key developmental understanding, then Figure 1 becomes an important assessment item, potentially discriminating between a student who understands a fraction as an arrangement and one who understands a fraction as a quan-

tity. (This claim is made acknowledging the weakness of drawing conclusions from a single assessment item.)

Continuing the comparison of these two views of understanding, a conventional approach to a student's difficulty with a problem is to ask, "What is it that the student does not know?" The approach based on key developmental understandings is to ask, "How is the student who can solve the problem different from the student who cannot?" This is a subtle, but important distinction having to do with whether the focus is on *the mathematics as seen by the one who understands it* or on *distinctions in the learners' understandings of the mathematics*. Again, let's use our fraction scenario. A response to the classroom situation might be to conclude that, "the students do not know that the shape of the one-half does not matter." This seems to describe the situation. Based on this conclusion, the intervention might encourage the students to cut up the triangular half and superimpose it on the rectangular half. This exploration might be expanded to other shapes and other fractions. The expectation would be that the students would eventually conclude that the shape of the fraction is not important, that one-half of any shape is the same size. This intervention has many of the features associated with current mathematics education reform efforts, hands-on problem solving, student exploration, attention to patterns, and students drawing their own conclusions. However, what is missing is the key understanding that underlay differences in the students' response to the original task.

The students who originally claimed that the halves were the same did not make that claim because they had cut up a rectangular half previously, nor because they were visualizing such a cut. They knew instantly and with certainty that the halves had to be the same size. The pedagogical intervention that involves cutting up the triangle is aimed at getting students to *know that* the two halves are in fact the same size. The intervention does not engender the anticipation that they *must be* the same size. That is, the intervention does not deal with conceptualizing that the result of equal partitioning is a new unit that has a fixed relationship to the original unit (whole). Tzur (1999) described a teaching experiment with students aimed at promoting this key understanding. Because it is focused on an underlying understanding that is key to the students' development with respect to fractions, the interventions are quite different from the fraction-cutting activity described in the preceding paragraph.

The type of question asked by one who is interested in key developmental understandings, "How is the student who can solve the problem different (conceptually) from the student who cannot?" leads to a particular type of inquiry. For example, one of the more intractable problems in mathematics education is how to foster growth in students who use an additive comparison for situations involving multiplicative comparisons (ratio). Defining ratio and creating lessons to make sure students have all facets of the definition are not likely to foster the understanding needed. An inquiry into the (developmental) differences between the student who can identify multiplicative comparisons and the one who cannot (or cannot for particular types of situations) is more likely to produce a breakthrough in this area.

The construct that I have proposed in this paper does not represent an area of inquiry that is without precedent in mathematics education. Rather it offers an abstraction of productive activity that has gone on in particular research projects on particular mathematical topics. With this abstraction, we can examine current research, curricula, and teaching. With respect to research, much more research into key developmental understandings is needed in most mathematics content areas. When we examine available curricula, including recent reform-based curricula, we generally do not see an orientation toward key developmental understandings. Finally, thinking in terms of key understandings is not commonplace among teachers of mathematics at any level. This is a potentially important focus for mathematics teacher education.

# **RE-CONCEPTUALIZING PROCEDURAL KNOWLEDGE: THE EMERGENCE OF “INTELLIGENT” PERFORMANCES AMONG EQUATION SOLVERS**

Jon R. Star  
Michigan State University  
jonstar@msu.edu

This paper explores the development of students' knowledge of mathematical procedures. Students' tendency to develop rote knowledge of procedures has been widely commented on. I postulate an alternative, more “intelligent” endpoint for the development of procedural knowledge, where students choose to deviate from established solving patterns on particular problems for greater efficiency. The purpose of this study was to explore the instructional conditions that facilitate the emergence of this outcome. Students with no prior knowledge of formal linear equation-solving techniques were taught the basic transformations of this domain. After instruction, students engaged in problem-solving sessions in two conditions. In the treatment group, students completed “alternative ordering tasks,” where they were asked to re-solve previously completed problems but using a different ordering of steps. Completing alternative ordering tasks was found to lead to more intelligent solving.

## **Introduction**

For much of this century, mathematics educators have sought to address students' tendency to view school mathematics as a series of procedures to be memorized. Researchers in mathematics education concur that (a) procedures learned by rote are easily forgotten and error-prone; and (b) the learning of procedures must be connected with conceptual knowledge in order to foster the development of understanding (e.g., Hiebert & Carpenter, 1992). The National Council of Teachers of Mathematics (NCTM) has articulated this emphasis on conceptual learning by calling for decreased attention to “memorizing rules and algorithms; practicing tedious paper-and-pencil computations; memorizing procedures ... without understanding” (NCTM, 1989, p. 71); and “rote memorization of facts and procedures” (NCTM, 1989, p. 129).

There is little doubt that the rote execution of memorized procedures does *not* constitute “mathematical understanding.” However, there are other ways in which a procedure can be executed other than by rote, some of which could be characterized as “intelligent” or even as indicative of “procedural understanding” (Greeno, 1978). But few prior studies have considered procedural outcomes other than rote knowledge, much less explored its development. This paper attempts to map out this terrain: I examine the development of students' knowledge of mathematical procedures, with particular emphasis on examining learning outcomes other than rote execution.

## **Perspective**

Fundamentally, executing a procedural skill requires that one have knowledge of its component steps and the order in which these steps should be applied. But not all performances of a skill are the same. In particular, skillful execution in mathemat-

ics can mean two very different things. On the one hand, skillful execution involves being able to use procedures rapidly, efficiently, with minimal error, and with minimal conscious attention; in other words, to execute a procedure automatically or by rote (Anderson & Lebiere, 1998). On the other hand, being “skilled” means being able to select appropriate procedures for particular problems, modify procedures when conditions warrant, and explain or justify one’s steps to others; that is, to execute a procedure thoughtfully or deliberately (Ericsson & Charness, 1994; Karmiloff-Smith, 1992), “relationally” (Skemp, 1976), “mindfully” (Brown & Langer, 1990; Langer, 1993), or “intelligently” (Ryle, 1949).

Although acknowledging that both notions of “skilled” are important and necessary (National Research Council, 2001), mathematics educators have had difficulty integrating these two competing visions of mathematical proficiency. The tension between these two visions is a foundational issue in mathematics education: it not only pertains to our educational goals for students, but also speaks directly to what it means to know and to do mathematics.

While the first outcome for successful skill execution (automaticity) has been frequently examined by cognitive scientists (Anderson, 1982; Anderson & Fincham, 1994; Anderson & Lebiere, 1998), “intelligent” execution of procedures has been less widely studied and is thus the focus of this paper. I begin by articulating what I mean by intelligent execution of procedures. I then describe a study that explored the development of this capacity.

### Framework

What does it mean to intelligently execute procedures?). I have proposed elsewhere that two central features of intelligent execution of procedures are (a) flexibility, and (b) innovation (Star, 2001a, 2001b). Flexibility refers to the ability to use a wide range of mathematical procedures in order to generate the best solution for particular problems (Beishuizen, van Putten, & van Mulken, 1997; Feltovich, Spiro, & Coulson, 1997). Flexible solvers have knowledge of standard solution procedures, but they also choose to use alternative or non-standard procedures on certain problems, when doing so results in a better or more efficient solution. Metaphorically, flexible solvers have more tools in their procedural toolbox.

Another feature of intelligent execution is innovation (Gick, 1986; Ryle, 1949; Simon & Reed, 1976). Innovation refers to the ability to use steps within a procedure in atypical ways in order to produce a more efficient solution. An innovative solver is able to use the individual steps of a procedure in ways other than that suggested by a standard solution. Metaphorically, innovation refers to the ability to use the tools in one’s toolbox in non-standard ways that do a better job of performing certain kinds of tasks.

Both innovation and flexibility can be seen in the example solutions shown in Table 1. Note that the three problems in Table 1 are almost identical, but they have been solved using three different solution strategies. Problem A is solved using a standard solution method, one that is commonly and explicitly taught as *the* way to solve

linear equations in US schools. Problems B and C could have been solved using this exact same method, but the solver has recognized and capitalized on the opportunity to use different strategies for these two problems -- strategies that are at least as good as the standard method but that could not be used in problem A. A solver who chooses to use the three solution strategies shown in Table 1 on this set of three problems is demonstrating flexibility; she has knowledge of multiple solution procedures and can select the most appropriate one for a particular problem.

**Table 1.** Example Solutions to Three Linear Equations

Problem A:

$$\begin{aligned} 4(x+1) + 2(x+2) &= 3(x+4) \\ 4x+4 + 2x+4 &= 3x+12 \\ 6x+8 &= 3x+12 \\ 3x &= 4 \\ x &= 4/3 \end{aligned}$$

Problem B:

$$\begin{aligned} 4(x+1) + 2(x+1) &= 3(x+4) \\ 6(x+1) &= 3(x+4) \\ 6x+6 &= 3x+12 \\ 3x &= 6 \\ x &= 2 \end{aligned}$$

Problem C:

$$\begin{aligned} 4(x+1) + 2(x+1) &= 3(x+1) \\ 6(x+1) &= 3(x+1) \\ 3(x+1) &= 0 \\ x+1 &= 0 \\ x &= -1 \end{aligned}$$

Innovation can be seen by looking closely at the solution steps used in problem B. In her first step, the solver has combined the terms  $4(x+1)$  and  $2(x+1)$  to yield  $6(x+1)$ . The way that this solving step, "combining like terms," is more typically used is to combine variable terms (such as  $4x$  and  $2x$ ) or constant terms (such as 4 and 2), as was done in the standard solution method seen in problem A. In problem B (and also in problem C), the solver has used the same "combine like term" step, but in an atypical way that results in a solution that is arguably better. This atypical or non-standard use of an equation-solving step is what is meant by innovation.

Framing intelligent equation-solving in this manner raises the question of how innovation and flexibility develop. This question is largely unexplored. Basic skill practice has been linked to the development of rote knowledge (Anderson, 1982; Fitts, 1964), but the development of more flexible knowledge appears to require a different kind of practice,

which has been referred to as "deliberate" (Ericsson, Krampe, & Tesch-Romer, 1993). One hypothesis for what such deliberate practice looks like comes from studies where participants were asked to solve a problem repeatedly in order to observe changes in their solutions that emerged with practice. There is ample evidence that solving a problem multiple times can lead to more automatic execution (e.g., Simon & Reed, 1976; Anzai & Simon, 1979; Blessing & Anderson, 1996; Koedinger & Anderson, 1990). However, there is also reason to hypothesize that, under certain conditions, re-solving previously completed problems can lead to more intelligent solving (Blöte, Klein, & Beishuizen, 2000; Krutetskii, 1976).

In the present study, I test this hypothesis by utilizing a task I refer to as the "alternative-ordering task." Participants are asked to re-solve previously completed problems but using a different ordering of steps. In this task, students are not merely

practicing the same solution over and over again, but instead are generating, comparing, and evaluating the effectiveness and efficiency of different solution procedures. There is reason to speculate that such a task may lead to more intelligent solving, in the form of greater innovation and flexibility.

### Goals

In my prior work (Star, 2001a, 2001b) I demonstrated that intelligent execution of procedures, as described above, exists in school-aged learners, and I explored the development of this capacity among solvers working individually on a paper-and-pencil task. In the present work, I build upon these initial findings by examining the development of intelligent execution among groups of students in a simulated classroom setting.

### Method and Data Sources

Thirty-six 6th grade students volunteered to participate in this study. Students attended one-hour experimental sessions in groups of six for five consecutive days. The mathematical domain that I chose to use in this study was linear equation solving. A pre-test on linear equation solving was administered on Day 1. Students were then given a brief 30-minute scripted lesson on the steps used to solve linear equations (e.g., adding a constant to both sides of an equation, adding like terms, etc.). Following instruction, students were given a post-instruction test on these steps.

At the conclusion of instruction, all six students were randomly assigned to a treatment or a control group. Both groups devoted the sessions on Days 2, 3, and 4 to equation-solving practice. During these three problem-solving sessions, students solved a great variety of equations, some of which were very straightforward (e.g.,  $2x + 4 = 10$ ), while others were much more complex (e.g.,  $4(x + 2) + 6x + 10 = 2(x + 2) + 8(x + 2) + 6x + 4x + 8$ ).

In the problem-solving sessions, students engaged in alternating cycles of individual work followed by group discussion. The treatment and control groups differed only in the content of the group discussion. In the treatment groups, the discussion centered on students comparing their solution methods, discussing the differences between solution methods, and generating alternative solution methods. In the control groups, students participated in a discussion of identical length and concerning the same problems. However, the discussion focused on the correctness of numeric solutions and methods of checking numeric solutions. On Day 5, students in both conditions were given a common post-test.

### Results

The most interesting result was that students in the treatment and control groups differed in the ways that they chose to approach equations by the end of the study. Significant differences emerged in both students' flexibility and innovation.

With respect to flexibility, treatment students were significantly more likely to become flexible solvers than control group students: In particular, treatment students

were more likely to use several different solution methods on the post-test problems, while control students were more likely to rely upon a single solution for all problems. The repeated equation-solving practice that control group students received resulted in the discovery, for each individual, of a dependable, favorite solution method that was used on many subsequent problems. Sometimes a student's favorite solution method was an efficient one; however, in other cases, students reliably and consistently used solution methods that were quite inefficient. For example, Table 2 shows the solution strategy that Billy (a student in the control group) used on several problems toward the end of the study. Billy repeatedly moved variable and constant terms back and forth, from one side of the equation to the other. Despite the inefficiency of this approach, it is one that Billy used consistently. In contrast, treatment students, ostensibly because they were repeatedly asked to consider alternative ways that equations could be solved, did not settle into a favorite, consistently used solution strategy. Rather, treatment students varied the ways that equations were solved in the post-test depending on the specifics of individual problems, demonstrating knowledge of multiple solution strategies. Treatment students were not content merely to solve an equation using an algorithm that was known to always work for them; they tried multiple approaches in order to arrive at the best solution for a particular problem.

**Table 2.** Billy's Solutions to Problem 4.2

|        |   |
|--------|---|
| Billy: | $3(x + 1) + 6(x + 1) + 6x + 9 = 6x + 9$ |
|        | $3x + 3 + 6x + 6 + 6x + 9 = 6x + 9$     |
|        | $3 + 6x + 6 + 6x + 9 = 3x + 9$          |
|        | $3 + 6x + 6 + 6x = 3x$                  |
|        | $3 + 3x + 6 + 6x = 0$                   |
|        | $3 + 6 + 6x = 3x^a$                     |
|        | $3 + 6 + 3x = 0$                        |
|        | $6 + 3x = -3$                           |
|        | $3 + 3x = 0^*$                          |
|        | $3x = -3$                               |
|        | $x = -1$                                |

<sup>a</sup>Indicates an error in how a transformation has been applied.

This increased flexibility appears to be related to innovation: there is evidence that treatment students in this study were more likely to innovate than control group students. Recall that innovation is the use of an equation-solving step in an atypical way that results in a better solution for a particular problem. 81% of treatment students showed signs of emerging innovation on at least one problem attempted during the 3 problem-solving sessions, while only 15% of control group students did

so. Innovation is illustrated in Table 3, which shows Anna's (a student in the treatment group) solutions to equations she encountered in the second and third problem-solving sessions. Note the difference between how Anna solved problems 2.2 and 3.2, two problems that are structurally identical. Anna's solution on problem 3.2 is more efficient than the one used on problem 2.2, in that she chose to divide to both sides as a *first* step (on 3.2) rather than a last step (on 2.2). (Dividing to both sides as a last step

is the typical way that students solved equations such as this one.) Anna's use of the "divide to both sides" step" atypically is an example of an innovation. Anna came to this knowledge as a result of the treatment: the generation, comparison, and reflection on multiple solution strategies. Control group students were significantly less likely to produce innovative solution strategies such as this one illustrated in Table 3.

### Discussion

This study provided evidence that engaging in alternative ordering tasks, which involved re-solving previously solved equations using a different ordering of steps, led students to believe that equations could be solved in more than one way and that some strategies were better than others. Treatment students'

cognizance of multiple ways that equations can be solved led to an increase in their ability to innovate, where innovation refers to the use of a step in an atypical way that results in a better solution. The ability to innovate was also related to increased flexibility in treatment students' solutions, where flexibility refers to a reluctance to rigidly adhere to the exact same solution sequence when solving similar problems. Students who did not experience this treatment were more likely to develop one solution method that was rigidly adhered to on all problems.

This study adds to the literature on equation solving by shifting the focus from students' errors to the capacities that successful performers exhibit. A review of the literature on the use of mathematical procedures (with its emphasis on cataloging the multitude of errors that students make) suggests that the most important feature of success in this domain is the ability to rapidly execute error-free procedures. The present study suggests that another important feature of a successful solver is the ability to intelligently use procedures; that is, to selectively choose to deviate from standard and practiced methods in order to produce even more efficient solutions. Students who have capacities for innovation and flexibility have more sophisticated knowledge of equation solving transformations that only emerges in their application. This outcome of learning procedures has not previously been considered in the mathematics education literature.

*Implications.* The fact that the alternative ordering task was effective in this study suggests that these results could be used to inform classroom practice in several ways. First, during instruction on equation solving (and other symbolic mathematical procedures), teachers should frequently and regularly ask students to re-solve previously completed problems using a different ordering of steps. The multiple solutions that are

**Table 3.** *Anna's Solutions to Problems 2.2 and 3.2*

|                     |                 |
|---------------------|-----------------|
| <i>Problem 2.2:</i> | $3(x + 1) = 15$ |
|                     | $3x + 3 = 15$   |
|                     | $3x = 12$       |
|                     | $x = 4$         |
| <i>Problem 3.2:</i> | $3(x + 2) = 21$ |
|                     | $x + 2 = 7$     |
|                     | $x = 5$         |

generated in such a task can then be compared and contrasted. The study described in this paper suggests that the incorporation of such tasks will result in substantial gains in students' ability to innovate and be flexible.

Implicit within this recommendation is a caution *against* direct and explicit instruction on the "standard solution method." Especially for novice learners, teachers should avoid labeling any one solution method as being the best way, the right way, or the only way. Benefits that arise from engaging in the alternative ordering tasks come when students think carefully about how to generate additional solution strategies and how to compare multiple solution strategies. Students come to their own conclusions about the features that identify one solution as different from another (e.g., efficiency), and direct instruction on a standard, efficient procedure would appear to subvert this process.

A challenge that necessarily accompanies these recommendations concerns student motivation. Many teachers find students to be uninterested in learning how to solve equations, and so it might appear that asking students to re-solve previously completed equations would further reduce already low levels of motivation. This is certainly a valid concern. However, there is a great deal of evidence from the elementary grades that such concerns can be addressed. Many examples exist of classrooms where a climate has been created that incorporates the features that are integral to the recommendations detailed above: student collaboration, the sharing of multiple solution strategies, and the group comparison and evaluation of mathematical procedures and reasoning (Ball, 1993; Chazan & Ball, 1999; Lampert, 1990). There are fewer examples of this kind of classroom environment at the high school level, particularly related to the instruction of mathematical procedures. The study described here suggests that there is much to be gained from efforts to make such changes at the secondary level.

### Conclusion

Procedures are an integral component of mathematics. While fluency is certainly one educational outcome, this paper has identified another in the ability to vary the ways that one uses procedures on particular problems in order to arrive at maximally efficient solutions. Krutetskii captured this distinction as follows:

Incapable students are marked by inertness, sluggishness, and constraint in their thinking in the realm of mathematical relations and operations. ... Mathematically able students are distinguished by a greater flexibility, by mobility of their mental process in solving mathematical problems. It is expressed in a free and easy switching from one mental operation to another qualitatively different one, in a diversity of aspects in the approach to the problem to problem-solving, in a freedom from the binding influence of stereotyped, conventional methods of solution, and in the ease in reconstructing established thought patterns and systems of operations. ... Very typical of capable students is a striving for the most rational solution to a problem, a search

for the clearest, simplest, shortest, and thus most 'elegant' path to the goal. (Krutetskii, 1976, p. 282-3)

While incapable students -- those with rote knowledge of procedures -- are relatively easy to find, intelligent solvers present a much more significant challenge. The study described in this paper represents a first attempt to re-conceptualize procedural knowledge so as to include such a relational outcome. If flexibility and innovation in the use of procedures are integral to our educational goals for students, further investigation of the development of this kind of procedural knowledge is vital.

# **STUDENT-TO-STUDENT QUESTIONING IN THE DEVELOPMENT OF MATHEMATICAL UNDERSTANDING: SIX HIGH SCHOOL STUDENTS MATHEMATIZING A SHELL**

Janet G. Walter  
Brigham Young University  
jwalter@mathed.byu.edu

Carolyn A. Maher  
Rutgers University  
cmaher@rci.rutgers.edu

This paper describes the nature of student-to-student discourse questioning as learners construct a mathematical model for the growth of a spiral shell. Students' natural language becomes mathematically formalized as students' questioning patterns evolve. Questions posed by students are viewed as pivotal mechanisms in students' discursive drive toward building deep understanding.

This paper describes continuing research on the nature of student-to-student discourse questioning as learners negotiate and assimilate strategies to construct a mathematical model for the growth of a spiral shell.<sup>1</sup> Research on the use of language by students doing mathematics has generally been framed by classroom contexts and uniquely developed symbolic systems. Student discourse as negotiation of mathematical understanding has been described as being grounded in the situated social context of a classroom. However, little attention has been paid to specific linguistic aspects of students' natural<sup>2</sup> language use in mathematical reasoning that give rise to mathematical language and understanding within a classroom domain (Morgan, 2000). Language structure patterns in mathematics classrooms evolve, as do structural patterns learned and used by speakers in the processing activity of language acquisition (Langacker, 1999). Language structure patterns within institutional contexts such as classrooms "appear to be characterized by asymmetric distribution of questions and answers among the participants" with questioning dominated by the teacher and answering identified with the role of student (Drew & Sorjonen, 1997).

Questioning in mathematics classrooms traditionally occurs when the teacher poses questions to students and occasionally, students may pose questions to the teacher. Significant research has been conducted on teacher questioning of students (Maher & Davis, 1990; Maher, Davis & Alston, 1992; Maher & Martino, 1992; Martino & Maher, 1999; Martino & Maher, 1994). Teachers whose practices include listening carefully to the language of students, following and fostering the growth of student ideas, may recognize distinctions between the kinds of questions students do ask. For example, teachers may interpret certain student questions as solicitations to the teacher to repeat a previous statement, or questions may be perceived as requests for the teacher's expert evaluation of student performance, queries for procedural instruction, or questions that suggest conditional possibilities.

Recently, research has shifted from teacher centered questioning, toward examining the significance of student-to-student questioning in the development of

mathematical understanding. This shift appropriately coincides with an increased emphasis in student centered learning as students propose mathematical ideas and actively engage in small group learning experiences (National Council of Teachers of Mathematics [NCTM], 2000). Current research, which investigates student interaction without teacher intervention, suggests that students ask distinctly different types of questions as they work together to build understanding and develop mathematical language and models (Walter, 2001). Central to this research is inquiry into how mathematical understanding is shaped and promoted by the structure of questioning patterns in student-to-student discourse.

### **Perspective**

One perspective on the learning of mathematics views human experience as situated and constituted within social contexts. This perspective minimizes the consideration of individual learning in isolation from the social contexts in which learning is situated. Therefore, from this point of view, individual knowledge is concurrently constructed with internalized social interaction.

Instructional environments affect learning and shape the ways and extents to which learners participate in classroom discourse. Discourse analysis contributes to our understanding of language as social filter (Brown, 2001). In other words, participation in a discourse is filtered by the extent to which a participant appropriates language and symbols peculiar to that discourse (Doerfler, 2000; Philips, 1988). Traditional classroom instructional environments often suppress mathematical discourse between students and filter out the experiencing of mathematics as active model building. Mathematics as model building is a central process in the work of professional mathematicians and a major thrust identified in the NCTM Principles and Standards (2000).

The development of mathematical language within student discourse may best be examined within the context of observable social factors. Therefore, the use of videotaped student interactions as one data source "can make visible subtle nuances in speech as well as non-verbal behaviors" (Powell, Francisco, & Maher, 2001). Thus, identification of subtle differences in student-to-student questions is made possible through analysis of student interactions captured on video. For the purposes of this paper, the issue of particular interest is how student-to-student question patterns evolve and influence the emergence of meaningful mathematical language.

### **Method**

Six high school students, working together in pairs or as a group, were videotaped with one camera. The videotapes were digitized, compressed, and saved as MPEG1 files. The video files were time-code linked with databases of video content description, critical events, verbatim transcript of student utterances and coded events within the qualitative research software vPrism (Walter & Maher, 2002; Powell et al., 2001). Video content descriptions were carefully created to broadly convey as objectively as

possible what occurred on video. These descriptions are important contextual referents and are included in the episodes presented here. Critical events were identified as specific video clips that captured and conveyed peculiarly significant utterances or behaviors germane to inter-student questioning and mathematizing the spiral. From the vantage created by selected critical events, analysis proceeded by re-examining what factors contributed to a particular event and what impact the event might or might not have had in subsequent student interactions.

Iterative re-examination of events is a principle feature for the development of detailed storylines in this qualitative model of analysis. During this process, codes were developed, modified, and refined to trace themes and patterns in student-to-student questioning. Differences in the nature of student questions became evident as question units were identified and contextually analyzed and re-analyzed. Question codes were developed to include: (QA) question that checks attunement between participants' understandings and seeks demonstrated mutual agreement; (QI) interrogative question for information that is not procedural; (QP) procedural question; (QC) confirmation request by participant regarding participant's own conceptual understanding, differs from attunement by not demonstrating concern for "the other's" understanding; (QS) speculative question that posits potential; and (QR) rhetorical question. Students' mathematical inscriptions and journal entries provided triangulation of data.

### Data and Analysis

This qualitative study presents analysis of several video vignettes of six high school students who were invited to participate with other students in a summer pre-calculus institute as part of a fourteen-year longitudinal study of children's mathematical thinking conducted by Carolyn A. Maher, Rutgers University. Students gathered for four hours each day for two weeks to do mathematics in a simulated classroom setting.

Students were presented with a sequence of open-ended mathematical modeling tasks during this time. One task involved polar coordinates, a topic with which most of the students had little experience<sup>3</sup>. The task featured a photocopy of a fossilized spiral shell that students held and inspected. The fossil had been sliced in half to reveal the intricate, segmented internal structure that anciently housed and protected the growing organism. Students were asked to find the center of the shell, draw a ray, organize a table of measurements and say what they could about " $r$  as a function of  $q$ ."<sup>4</sup> The modus operandi in the longitudinal study was for students to freely work with one another while researchers, taking field notes, respectfully observed. Students were customarily not given instruction on procedure or content, although a three-minute intervention did take place approximately twenty-one minutes after students began working on the task.

The six students spotlighted in this study developed three mathematical models. This paper presents an analysis of the evolution of questioning patterns in the first

forty-five minutes of student discourse during the initial development of one model, a tabular representation of concentric circles (Figure 1).

After the task was introduced, students spent the first seven minutes negotiating agreement on where the center of the spiral should be located, whether “r” represented radians or radius, and what “r as a function of theta” meant. Students asked twenty-five questions during this interval which were primarily attunement (10) and interrogative (9) questions. Attunement questions focused on agreement for the location of the center while interrogative questions attempted to refine understanding of what theta, radian, and radius meant. Students continued to refer to the written task as the authoritative source in justifying their ideas. Student language is very generalized, such as when Michelle refers to the center as “this little hole” and Angela refers to the spiral shell as “the thing”.

Students agreed to draw the ray “straight up” after locating the center of the spiral. The following excerpt demonstrates that the notion of radius was more difficult to resolve because it was not immediately apparent to the students whether “r” meant radius or “r” meant radians. Students discuss the meaning of r and theta and radians, and radius. They discuss which radius should be measured.

- |          |          |   |
|----------|----------|---|
| 12:08:28 | Michelle | What can you say about r as a function of theta? Like if you have like say two radians, what does r stand for? (QI) |
| 12:25:18 | Robert   | Radians   |
| 12:27:17 | Michelle | Well, no, isn't that theta, isn't theta the radians? (QC)   |
| 12:31:27 | Angela   | r is radius, is it not? (QC)  |
| 12:34:01 | Sherly   | That's what I thought.  |
| 12:35:10 | Michelle | Okay, but what's theta? (QI) It can't be measured in degrees.   |
| 12:39:02 | Sherly   | They want theta.  |
| 12:40:19 | Robert   | You gotta measure in radians  |
| 12:42:08 | Michelle | Right, so   |
| 12:44:00 | Angela   | Why can't you measure in degrees? (QS)  |

Figure 1. Students' initial representation for concentric circle model of spiral shell.

- 12:46:04 Sherly 'Cause it says lets measure distance in centimeters and angles in radians.
- 12:50:24 Robert And something about like it depends on, um,
- 12:53:23 Angela Alright, well, what's the radius of this thing? (QI)
- 12:57:18 Robert That's what we've got a ruler for.
- 12:59:22 Sherly 'Cause we could do this one or you could do like the whole thing.
- 13:03:14 Michelle Yeah, but its still not the whole thing.
- 13:04:10 Sherly That's true.
- 13:10:03 Michelle Maybe it means from the center to the outside. [Michelle suggests they measure from the center to the outside. Ashley asks a question to which Michelle responds.]
- 13:13:19 Sherly Wait, you could also go from the center to that. [Sherly points to the copy of the shell with her pen.]
- 13:15:25 Angela It's a spiral, it keeps going. It doesn't have a radius.

Angela's language changed, as she referred to the spiral instead of "the thing" while Michelle and Sherly continued to refer to the spiral as "thing". Angela pointed out that a spiral does not have a radius; it just "keeps going". These students had limited experience with polar coordinates, but had stronger intuitions about radii and circles. Perhaps Angela's understanding of radius and circle prompted the mathematical refinement of her language by requiring distinctions between "circle" and "spiral".

As discussion continued, Michelle suggested that they measure along the ray from the center of the spiral to various points where the ray intersected the spiral. Angela agreed and each student then traced the spiral and began measuring various lengths along the ray in centimeters. Question types alternated between interrogative and attunement when it became apparent that different measurements were being obtained. Michelle exclaimed that she had a brainstorm and turned toward Robert to share her idea. Students' language patterns include overlapping conversations, reflected in the excerpt presented here.

- 18:23:01 Michelle Oh, I have an idea! I have a brainstorm.
- 18:27:21 Sherly Okay, what does table r as a function of theta mean? (QI) Bob! [Sherly directs her question to Robert.]
- 18:32:12 Michelle Okay, let me explain it to you 'cause you'll probably understand me. [Michelle attracts Robert's attention by reaching out toward him with her right hand as she speaks. She proceeds to explain her idea. Both students lean toward the table and each other as they speak.]

- 18:35:12 Michelle Okay, say this is point five, right? (QA) [Michelle and Robert are leaning forward and Michelle is gesturing with her pen in a circular motion on top of the photocopy of the spiral. She looks directly at Robert and smiles as she asks her question.]
- 18:38:22 Michelle And say that was the circle or whatever, would we measure...like.. radians? (QS)
- 18:45:18 Victor It's what...circle...what [Victor is talking with Sherly in another conversation.]
- 18:47:02 Michelle It would be point five centimeters right? (QC) Around the circle.
- 18:50:12 Victor Ooohh
- 18:51:26 Robert But there's like, isn't there like six pi radians and
- 18:56:29 Sherly What
- 18:57:17 Robert Should it just be six pi times point five? (QI) I don't know. [Robert asks for information about what the answer should be.]
- 19:00:15 Michelle No, it's two pi radians
- 19:02:10 Ashley Yeah
- 19:02:23 Victor It's what? (QI) [Victor now participates in the conversation between Michelle and Robert.]
- 19:04:03 Sherly Yeah, two pi radians [Sherly supports Michelle's assertion.]
- 19:05:17 Robert Yeah, yeah, two pi... [Robert, Michelle and Sherly determine that there are two pi radians in a circle.]
- 19:06:07 Sherly Good job.
- 19:07:07 Robert ..'cause its six point somethin'. [Robert represents pi as a decimal.]
- 19:11:12 Sherly Wait. Can we just stop for a second? ... see where we're heading? (QA)
- 19:15:00 Robert So do we just take that and multiple it by the point five? (QP) [Robert asks again if they multiply by point five, this time as a procedure.]
- 19:18:27 Victor Yeah, that's right

- 19:19:24 Michelle I don't know
- 19:21:09 Angela No, cause its not like it's like a circle. Its not. It's a spiral. Its not a... [Discussion about using a circle vs. spiral. Angela disagrees.]
- 19:26:03 Robert It doesn't matter.
- 19:27:18 Michelle I don't think...I know it's not perfect, but I think that everyone should just, you know, assume, say it is a circle. So why don't we have one circle that's point five centimeters and then one circle with one point two centimeter radius? (QS) [Here is the stated beginning of a model that develops into the final model presented by the group, even though Michelle is absent the next two days.]
- 19:40:11 Angela Well, see then it will be like, you know. [Angela explains why she doesn't agree with Michelle's idea. She draws four concentric circles.]
- 19:44:19 Michelle Yeah, but doesn't matter.

Michelle articulated a model for the spiral—circles with different radii—as a speculative question. Although Angela initially disagreed, it was this concentric circle model that the group developed for their final presentation given three working days later. Members of the group also constructed two other models over the next three days as students continued to work and ideas were shared between groups.

The following excerpt demonstrates that careful analysis of questioning in discourse between students depends on context. Questions taken out of context may appear to be identical in nature when they are different utterances since they function differently.

- 50:28:14 Sherly See, look, its sixty degrees. So, sixty degrees is how many radians? (QI) [Sherly is looking at her calculator and speaks to Victor. Victor is looking at his calculator, leans over and looks at Sherly's and says, "Yeah, um, that means."]
- 50:31:04 Angela I'm sorry. What did you say? (QI) [Angela responds to Michelle. Conversations between individuals are overlapping.]
- 50:32:27 Michelle I'm saying, go out with another line
- 50:35:02 Victor Sixty degrees is how many radians? (QR) Well [Victor repeats Sherly's question and then picks up a calculator.]

50:41:19 Victor Sixty degrees times, uh, pi over one-eighty degrees. [Victor explains and Sherly is first looking down and then looks up toward the ceiling and rolls her eyes wide from side to side as she listens.]

Sherly's question, "Sixty degrees is how many radians?" was an interrogative for information. Victor's question was rhetorical since he was repeating Sherly's question verbatim rather than asking the question as an original interrogative.

### Results

During the first forty-five minutes working on the Placenticerias task, students asked one hundred forty-eight questions. Forty-four percent were interrogatives, twenty-three percent were attunement, sixteen percent were procedural, seven percent were confirmative, seven percent were speculative, and three percent were rhetorical. As discourse developed over time, the distribution of question types changed. Prior to Michelle's speculative question about using concentric circles to model the spiral, forty-seven questions were posed. Thirty-eight percent of those forty-seven questions were attunement, thirty-six percent were interrogative, eleven percent were procedural, eight percent were speculative, and six percent were confirmative. After the notion of concentric circles as a model was introduced, until the session concluded, students asked one hundred one questions, forty-eight percent were interrogative, nineteen percent were procedural, sixteen percent were attunement, seven percent were confirmative, six percent were speculative and four percent were rhetorical.

Students' natural language became mathematically formalized as students distinguished between meanings for radius, radians, and spiral. Questions posed by students are shown here to be active, pivotal mechanisms in students' discursive drive toward building deep understanding. Under certain circumstances, student-to-student questioning patterns probe beyond procedure to identify mathematical relationships and develop meaningful representations.

As research continues to investigate student-to-student interactions, new insights may be gained into the structure of student discourse, the kinds of questions that students ask in constructing mathematical knowledge, and how teachers might tailor practice to capitalize on the kinds of questions students ask and facilitate development of mathematical understanding in classroom situations. This research has important implications, linked to classroom practice, that procedural instruction in mathematical modeling does not adequately address the nature of student questions, particularly with respect to the ways that these precalculus students build mathematical understanding.

### Notes

<sup>1</sup>This work was supported in part by National Science Foundation grant #REC-9814846 (directed by C.A. Maher) to Rutgers, The State University of New Jersey.

Any opinions, findings, conclusions, or recommendations expressed in this publication are those of the authors and do not necessarily reflect the views of the National Science Foundation.

<sup>2</sup>Use of the word “natural” refers to the circumstances in which researchers are not directly instigating student discourse. Interviews of students by researchers would not be considered natural student language (Wood & Kroger, 2000).

<sup>3</sup>After reading through the task, one of the students spontaneously remarked that five of the six students had studied polar coordinates for one day during precalculus math class the prior year.

<sup>4</sup>Robert Speiser, Brigham Young University, developed this task, Placentieras, for an honors calculus course.

# DEVELOPING STUDENTS' UNDERSTANDING OF EXPONENTS AND LOGARITHMS

Keith Weber  
Murray State University  
keith.weber@murraystate.edu

In this paper, we describe instruction designed to teach students about exponents and logarithms and report a pilot study to test the effectiveness of this instruction. Based on the theoretical work of Dubinsky and Sfard, we postulate a set of mental constructions that a student could make to understand the concepts of exponents and logarithms. We then describe computer and paper-and-pencil exercises designed to induce students to make these constructions. We report a pilot study assessing the efficacy of these exercises. Students receiving our instruction outperformed students receiving traditional instruction across a variety of measures, including performing basic computations, recalling formulae, explaining why rules of exponents and logarithms are true, and answering conceptual questions.

## Introduction

Exponents and logarithms are important mathematical concepts that are useful for modeling and understanding population growth, radioactive decay, and compound interest. Further, exponential and logarithmic functions are central concepts for many college mathematics courses, including calculus, differential equations, and complex analysis. Unfortunately, research indicates that students' understanding of these concepts is quite limited (e.g., Confrey & Smith, 1995). In particular, students often forget many properties of exponents and logarithms shortly after they learn them and can seldom explain why these properties are true (Weber, in press).

While mathematics educators have proposed instructional techniques to supplement or replace traditional pedagogy of exponents and logarithms (e.g., Confrey & Smith, 1995; Rahn & Berndes, 1994), to our knowledge, the efficacy of these techniques has not been assessed. The purpose of this paper is to describe instruction designed to teach students the concepts of exponents and logarithms and to report a pilot study in which we tested the effectiveness of this instruction.

## Theoretical Framework

Students are often told that the exponential operation represents "repeated multiplication" (e.g.,  $2^3 = 2 \times 2 \times 2$ ). However, as many researchers have pointed out (e.g., Confrey & Smith, 1995; Lakoff & Nunez, 2000), this conception is inadequate to perform much of the reasoning that we associate with exponents and logarithms. For instance, to a student who can only view exponents as repeated multiplication, expressions such as  $2^{-1}$  and  $2^{1/2}$  will be nonsensical, as you cannot multiply a number by itself negative one or one half times. In this paper, we attempt to teach students about exponents and logarithms by first having students understand exponentiation as a process,

then having them view exponential and logarithmic expressions as results of applying this process (i.e.,  $b^x$  represents the number that is the product of  $x$  factors of  $b$ ), and finally generalizing this understanding for cases where the power in an exponent is not a natural number. We discuss the theoretical underpinnings behind these constructions below.

According to Dubinsky, a mathematical operation can be understood as an action or as a process (Dubinsky, 1991; Asiala et al., 1996). An *action* is a repeatable physical or mental transformation of mathematical objects to obtain other objects. Students limited to an action understanding of an operation can apply this operation only in response to an external cue explicitly detailing what steps to make. In the case of exponents, students with only an action understanding can do little besides calculating an exponent when they are given a specific base and power, and only if the power is a positive integer. After repeating an action and reflecting upon it, the student may interiorize the action as a *process*. Individuals with a process understanding of an operation can imagine the result of the transformation without actually performing the corresponding operation and can construct a new process by reversing the steps of the original transformation. A student with a process understanding of exponents can imagine  $b^x$  as a number that is the result of applying the operation of exponentiation, an ability that we believe is necessary to understand the rules of exponents, and can imagine reversing the process of exponentiation to obtain the process of taking a logarithm.

Many researchers have noted that expressions such as  $b^x$  have multiple meanings: this expression can be viewed as an operation- multiply  $b$  by itself  $x$  times- or it can be viewed as a mathematical structure- the number that is the result of applying the process of exponentiation. It can also be viewed as a function, a family of functions, or a string of symbols, depending on the context in which it is used (e.g., Sfard & Linchevski 1994). In particular, Sfard (1991, Sfard & Linchevski, 1994) distinguishes between an operational understanding of a concept- which focuses on its algorithmic nature- and the structural understanding of a concept- which treats the result of a process as an object in its own right. While students are generally capable of acquiring an operational understanding of a concept, acquiring a structural understanding appears to be quite difficult. In our view, an operational understanding of exponents would be tantamount to understanding exponential expressions as calls for repeated multiplication, while a structural understanding would be interpreting  $b^x$  as *the number that is the product of  $x$  factors of  $b$*  and  $\log_b m$  as *the number of factors of  $b$  that are in the number  $m$* .

At this point, a critical reader may question why a student needs to understand  $b^x$  as a mathematical object. According to Sfard, possessing a structural understanding of mathematical objects is necessary to reason about mathematical concepts because it makes one's knowledge of the concept more compact and intuitive (Sfard, 1991, p. 23). We believe that this is the case with exponents and logarithms. Consider the

following rule about exponents:  $b^x b^y = b^{x+y}$ . A student with a structural understanding of exponential expressions could interpret this equation as “The product of  $x$  factors of  $b$  and  $y$  factors of  $b$  is  $(x+y)$  factors of  $b$ ”. Perhaps a student could also explain this equation as a statement about processes, at least in theory. (e.g., You obtain the same result if you multiply  $b$  multiplied by itself  $x$  times with  $b$  multiplied by itself  $y$  times or if you multiply  $b$  by itself  $(x+y)$  times). However, such an explanation would be longer and less intuitive. Hence, we believe that possessing a structural understanding of exponential and logarithmic expressions greatly aids students in understanding their properties.

After a student acquires an operational understanding of  $b^x$  as “the number that is the product of  $x$  factors of  $b$ ”, that student must generalize that understanding to account for cases where  $x$  is not a natural number. How students may do this is an interesting and difficult question, but it is beyond the scope of this paper. Discussion of this topic can be found in Confrey and Smith (1995), Lakoff and Nunez (2000), and Weber (in press).

### **Instruction Used in Our Study**

In this section, we describe instructional activities designed to lead students to make the mental constructions we describe above. After receiving this instruction, we would like students to be able to complete routine tasks that are traditionally associated with exponents and logarithms. That is, students should be able to perform basic computations with exponents and logarithms and be able to recite and apply the “rules” of exponents and logarithms. We would also like students to acquire a deeper conceptual understanding of these topics. Students should understand why the rules of exponents and logarithms are true and they should be able to use their conceptual understanding to answer traditional and non-traditional questions.

The first goal of our instruction is to have students understand the act of “taking an exponent” as a process (as described in section 2 of this paper or in Asiala et. al. (1996)). Research indicates that a particularly effective way for leading students to construct this understanding is to have students write a computer program to apply this operation. (Tall & Dubinsky, 1991). Researchers argue that in writing a computer program, students are forced to reason about and explicitly describe the steps of an operation. In doing so, students are likely to reflect on the steps of an operation and interiorize it into a process.

In our instruction, students were first taught the structure of a basic for loop and were given a for loop program in MAPLE that performed multiplication of integers as repeated addition (or repeated subtraction, in the case where a factor is negative). Students were asked to write a similar program that performed exponentiation as repeated multiplication (or repeated division). The students worked in pairs to write these programs. The instructor would answer questions and would help the students with MAPLE syntax, but would not help the students in other aspects of the program writing. All students completed this task in a one hour class period.

Our next goal was to have students understand  $b^x$  as the number that is the product of  $x$  factors of  $b$  and  $\log_b m$  as the number of factors of  $b$  that are in the number  $m$ , a construction that Sfard coins *reification*. Sfard (1991, 2000) emphasizes the role that names and symbols play in acquiring a structural understanding of a mathematical concept. We designed paper-and-pencil worksheets in which the student was asked to describe exponential and logarithmic expressions as mathematical objects. They were also given exercises in which they were required to use a structural understanding of the exponential expressions to complete. With the judicious use of worked out examples, the students had several prompts to help guide their work. Some examples of these exercises are given in the Appendix. Students worked in groups of two or three to complete these activities. After the activities were completed, they were discussed, handed in, corrected, and returned to the students. This continued until all the activities were complete.

A skeptical reader may question whether something as trivial as paper-and-pencil exercises and classroom discussion can trigger a mental construction as sophisticated as reification. The only response we can offer at this time is the results of our study indicate that it can. Students who received this instruction appeared to be more capable of treating  $b^x$  as a mathematical object than students who received traditional instruction. We will describe these results in the next section.

### **Evaluation of Our Instruction**

To evaluate the effectiveness of our pedagogy, we conducted a pilot study in which we implemented this instruction in a college algebra and trigonometry course and then compared the performance of our students with students who received traditional instruction on a set of interview questions.

### **Methods**

#### **Participants**

Two groups of students from a regional university in the southern United States participated in this study. The experimental group of students was enrolled in the first author's college algebra and trigonometry course. The control group of students was enrolled in a separate section of the college algebra and trigonometry course taught by a different instructor. The instructors of the control and experimental groups spent roughly equal time reviewing exponents and logarithms. 15 students in each course volunteered to participate in this study.

#### **Procedure and Materials**

Three weeks after receiving instruction, the students were interviewed individually. During the interview, the students were asked the following questions:

**Basic computations**

- B1. What is  $2^3$ ?
- B2. What is  $\log_2 64$ ?
- B3. What is  $\log_x x$ ?
- B4.  $\log_9 729 = 3$ . Use this information to find  $\log_3 729$ .

**Rules**

- R1.  $b^x b^y$  can be simplified to what? Why?
- R2.  $\log_a x^r$  can be simplified to what? Why?
- R3. How can you express the square root of  $x$  as a power? Why?

**Conceptual questions**

- C1. Is  $(1/2)^x$  an increasing function or a decreasing function? Why?
- C2. Is  $(-3)^{10}$  a positive or negative number? Why?
- C3. Is  $5^{14}$  an even number or an odd number?
- C4. How would you find  $\log_5 78125$ ?

**Results of the Pilot Study**

The number of correct responses for each of the Basic Computation and Rules questions is presented in Figure 1.

*Basic computation questions-* Every student was able to compute  $2^3$ , indicating that all participants had some basic notion of exponent. As can be seen from Figure 1, the participants in the experimental group performed much better than their counterparts in the control group on the remainder of the Basic computation questions. No student in the control group was able to answer questions B3 or B4.

*Rules questions-* The data in Figure 1 indicate that students in the experimental group were able to recall more rules of exponents and logarithms than students in the control group. The difference between the groups becomes more pronounced when one examines the students' responses when they were asked why the rules of exponents and logarithms were true. Not a single student in the control group was able to explain why any of the rules of exponents were true. However, students in the experimental group were often able to give an explanation of why the rules were true. For instance, eight students were able to explain why  $b^x b^y = b^{x+y}$ . One typical response from a student was "Because we're having  $b$   $x$  amount of time and  $y$   $x$  amount of time, so when you set it up...it's basically like your adding up all the repetitions of  $b$ ". Six students in the experimental group were able to explain why  $\log_b x^r = r \log_b x$  and why  $x = x^{1/2}$ . The latter result was particularly impressive, as why  $x = x^{1/2}$  was never explicitly discussed in our activities.

Figure 1. Performance on interview questions.

*Conceptual questions-* Both groups generally performed well on questions C1 and C2; they both were aware that  $(1/2)^x$  was a decreasing function and  $(-3)^{10}$  was a positive number. However, students in the experimental group were better at stating why these statements were true. When asked why the first property was true, no student in the control group could give an adequate response. Most students relied on looking at specific examples, usually only looking at the cases where  $x$  is one or two. However, five students in the experimental group were able to explain why this rule was true by using their understanding of exponentiation as a process. For instance, one student said, "If you keep multiplying [by one half], the number is going to keep getting smaller and smaller". Likewise, many students in the experimental group noted that the number  $(-3)^{10}$  could be decomposed into the product of positive numbers, while such responses from the control group were uncommon.

12 students in the control group believed that  $5^{14}$  would be an even number, generally because they believed an odd number raised to an even power would be even. The three students who correctly stated that  $5^{14}$  would be odd conjectured this by looking at simple cases such as  $5^1$ ,  $5^2$ , and  $5^3$ . 8 students in the experimental group also answered this question correctly. While four also did so by looking at simple cases, four other students offered deeper explanations such as, "An odd to any power is always going to be odd... 'cause you keep on multiplying by an odd number, so it can never turn even" and "It'll be odd. If you multiply two numbers ending in five, it's going to end in five. So 5 to the anything will end in five".

When asked how to compute  $\log_5 78125$ , eight students in the control group knew this was tantamount to solving the equation  $5^x = 78125$ , but none could offer anything more than this. In contrast, several students in the experimental group offered responses that demonstrated an understanding of logarithms as reversing the process of exponentiation. For example, four students suggested repeatedly multiplying by five until the result reached or exceeded 78,125 and another suggested dividing 78,125 repeatedly until he reached one. The number of repetitions required would be the answer.

*Reconstruction of forgotten knowledge-* Perhaps the most promising result from this pilot study was that students in the experimental group often could not recall properties of exponents and logarithms, but were able to use their conceptual knowledge of these topics to reconstruct these rules. For instance, three students in the experimental group initially believed that  $b^x b^y$  was equal to  $b^{xy}$ . (This was also a common mistake in the control group). When these students attempted to explain why this rule was true, they wrote out  $b^x$  as  $x$  factors of  $b$  and  $b^y$  as  $y$  factors of  $b$ . At this point, the students realized that there were  $(x+y)$  factors of  $b$  in  $b^x b^y$ , so the correct answer must be  $b^{x+y}$ . In contrast, this phenomenon did not occur with any of the students in the control group. In fact, not one student could explain why a single rule of exponents was true. There were several other instances of students in the experimental group using their conceptual knowledge to correct an initially erroneous response. For instance, one student initially believed that  $(1/2)^x$  would be an increasing function, but then realized that as  $x$  grows, "we are going to be taking half of it more often, so it will be getting smaller." This illustrates an important point. As time passes, one's knowledge of symbolic rules will generally decay. If one has a deep understanding of the concepts involved, these rules can be reconstructed. If not, the rules cannot be recovered.

## Discussion

### Summary of Our Data

Students who received our instruction performed better than students who received traditional instruction at performing basic computations, recalling rules, and explaining why the rules of exponents and logarithms are true. They were also better able to answer questions that required them to use their conceptual knowledge of these topics.

### Limitations of this Study

We consider the results of this pilot study to be encouraging. However, we should note that any conclusions drawn should be tentative, due to shortcomings in the design of this study. First, the author of this paper also served as the instructor of the experimental students and the investigator in the experiment. This raises a host of methodological concerns. Perhaps the instruction to the experimental students was superior to that of the control students, but only because the instructor of the former group of students was more motivated or more able. Perhaps the students in the experimental group performed so well in an effort to please or impress the investigator, who also

happened to be the individual who assigned their grades at the end of the semester. Students in the control group would feel no such obligation. Also, although there was no *a priori* reason to suspect that students in the experimental group had more knowledge of exponents and logarithms prior to instruction, this possibility cannot be dismissed since no pre-test was given to these students. Clearly these concerns need to be addressed before definite conclusions can be drawn.

*How do we know that the experimental students' performance was due to our instruction?* First, many of these students' responses were analogous to the way that they completed our worksheet. For instance, to answer question B4, one could simply combine several rules of exponents. (e.g.,  $\log_9 729 = 3$ . So  $9^3 = 729$ .  $(3^2)^3 = 729$ .  $3^6 = 729$ .  $\log_3 729 = 6$ ). However, not one student solved the problem this way. All 13 students who answered this question correctly wrote 729 as  $9 \times 9 \times 9$ , and then noticed that each 9 "split" into a pair of 3's so 729 can be written as  $3 \times 3 \times 3 \times 3 \times 3 \times 3$ . Thus there were six 3's in 729. The language that the experimental students used was also indicative of their thinking. For instance, many students spoke of there "being six threes in 729", indicating that students were thinking in a way that was consistent with our worksheets. Students' explanations of why the rules of exponents and logarithms were true were also consistent with their work on our worksheets.

Second, students' responses to our conceptual questions were consistent with our theoretical analysis. We predicted the conceptual questions could best be answered if the student had a process understanding of exponents. Many of the students' successful responses explicitly drew on this understanding.

### Conclusion

In the past decades, our understanding of how students acquire mathematical concepts has increased immeasurably. This study marks our first attempt to apply the influential learning theories of Dubinsky and Sfard into the classroom. Using their theories, we postulated a set of mental constructions that a student could make to understand exponents and logarithms. We then designed instructional activities to lead students to make these constructions. We described the results of a pilot study in which we assessed the effectiveness of this instruction. The results are encouraging; students who completed our instructional activities outperformed students who received traditional instruction in a variety of measures, including recall of formulas, simple computation, and specification of why the formulas are true. Perhaps most significant is that students can use their deep understanding of these topics to reconstruct forgotten symbolic knowledge. However, due to limitations in the design of our study, any conclusions drawn from this study should be tentative. We are attempting to replicate the results of our pilot study in a more controlled setting with more students. If our attempts are successful, this study will be the focus of a future report.

### Appendix

Sample exercises from our worksheet (Desired student responses given in **bold**).

Describe each of the exponential expressions in terms of a product and in terms of words.

$4^3 = 4 \times 4 \times 4 =$  **the number that is the product of 3 factors of 4**

$b^x = b \times b \times b \times \dots$  (**x times**) = **the number that is the product of x factors of b**

Simplify each of the expressions below by writing each exponential term as a product. Summarize each simplification in words.

$b^2b^4 = (b \times b) \times (b \times b \times b \times b) = b^6$

**The product of 2 factors of b and 4 factors of b is 6 factors of b.**

$bb^x = b \times (b \times b \times b \times \dots$  (**x times**)) =  $b \times b \times b \times b \times \dots$  (**x+1 times**) =  $b^{x+1}$

**The product of b and x factors of b is (x+1) factors of b.**

## THE COMPARISON OF TEACHERS' AND STUDENTS' ROLES IN TWO DIFFERENT TEACHING ENVIRONMENTS IN MATHEMATICS

Cigdem Haser  
Middle East Technical University  
chaser@metu.edu.tr

Behiye Ubuz  
Middle East Technical University  
ubuz@metu.edu.tr

The roles of the teacher and the students in grade five mathematics classrooms in two different teaching environments, one involving collaborative small-group work and the other involving conventional teaching, were analyzed in terms of their nature and circulation. The results of the analysis indicated that the student's role shifted from listener to active participant in different forms in the classroom. The role of the teacher, however, shifted from information giver to facilitator.

### Introduction

Roles in teaching and learning differ when mathematics is taught by different methods. In conventional teaching environment, there is a transmission of body of knowledge, independent of the learner, from the teacher to the students (Hoyles, 1985). The teacher asks the questions and directs the students, as the main decision-maker of the teaching. The teacher is responsible for the classroom and the materials, and maintaining the order (Cobb, Wood & Yackel, 1995).

The social interaction perspective considers mathematical understanding as ability to form, reflect and use a view of mathematical idea and combine several ideas into one's own framework, besides challenging and rejecting the several ideas in a logical base (Hoyles, 1985). Hence, mathematical meaning becomes a product of social interaction (Voigt, 1994) and discussion (Neyland, 1994).

In collaborative small-group learning, students are involved in a mutually established network of ideas and explanations for the given tasks (Damon & Phelps, 1989). Expert members are forced to listen to and reflect on the novice members' ideas and find a way of expressing the tasks to the novices in a communicatable way. Teachers are only facilitators in this process and, allow and encourage students to extend their abilities and take risks for new experiences and materials (Moll & Whitmore, 1998).

The purpose of this study is to investigate how the role structures in teaching mathematics change during the teaching of conceptual tasks by collaborative small-group learning. The groups formed on the conceptual tasks were mixed ability groups. The role structures in terms of the nature of roles and their distribution will be sought in order to understand how students can communicate the mathematical understanding effectively to others compared to the teacher's communication.

### **Method**

This study involves analysis of classroom interactions, particularly the roles of the teachers and the students in teaching in two classroom settings: One involving the collaborative small-group approach, and the other the conventional teaching approach. The experiment was carried out on fractions in both classes at the same time in 2000-2001 academic year. In conventional teaching class, the fractions were taught by conventional teaching approach, whereas in the collaborative small-group class, the fractions were taught by assigning the students to five-member collaborative groups.

The fractions in the grade five mathematics included the conceptual topics such as kinds of fractions, converting the fractions to each other, equivalence of fractions and ordering of fractions; and operational topics such as addition, subtraction and multiplication of fractions. The topics and their sequence, the exercise book and the homework assigned to the students were the same for both classes. The treatment in two classes was different only in terms of the method of instruction. In the collaborative small-group class the group worksheets prepared by the researchers were used. The students in two classes took the regular exams and the quizzes prepared by the school mathematics department.

The worksheets used in the collaborative small-group class were developed according to the findings of the literature review, the objectives of the National Curriculum, and the previous pilot study conducted in 1999-2000 academic year. The worksheets aimed to teach the fractions concepts and the operations with fractions by using the collaborative small-group approach. Students were required to work as a group on the tasks, such as writing rules or solving exercises, by making decisions by consensus, ensuring that all group members contributed their ideas and suggestions, and seeking assistance primarily from each other. Most of the worksheets were supported by manipulatives such as colorful unfolded cardboards representing the wholes, colorful pieces of cardboards representing fractions in continuous forms, and play dough representing fractions in discrete forms, to aid students' discussions with concrete examples.

### **Data Sources**

The study was conducted on two fifth grade classes, each with 30 students, in a private elementary school. Mathematics were taught by the same teacher. The lessons of both classes were tape-recorded. Here, one class session from each class was transcribed and examined as they are the representative of all other sessions. In the collaborative small-group class, the recorder was placed on a group's desk in order to gather data of group discussions when they work on the worksheets. Each lesson lasted 40 minutes. The classroom interactions in both classes were transcribed and used as data source. One class session of the two classes when the same concept was taught were focused to be interpreted. The possible roles that might likely to appear in the interac-

tions within the students, or between the students and the teacher in both classes were predicted in terms of teaching and learning components, such as explaining, questioning and confirming. The data were coded, recoded and reviewed by the researchers and final version of the codes was determined.

### Results and Discussion

In the conventional teaching class, the teacher has the dominant roles such as questioning, explaining and directing the discussion. She informed the students about the concept and related subconcepts by writing on the board before introducing the concept. Then, she asked questions or posed exercises to the students related with the definition or the concepts. The main role of the students in this class was limited to responding to the teacher's questions or writing the answer of the exercises on the board. The teacher either confirmed the students' responses, or warned them to correct their responses usually by directing the students by leading questions. Finally, the teacher generalized or summarized what she had talked about and asked students write the generalizations.

In the collaborative small-group class, however, additional roles such as gaining attention, initiating, explaining, correcting, confusing and conflicting appeared and all of the roles were shared among the group members during the group discussion. The students explained the tasks, posed questions to their friends and generalized the rules by discussion. The ones who did not talk in one task talked in the other, so the listener role as well as the explainer role seemed to change among the members. Even the students with lower ability level had the explainer role from time to time. All group members contributed to the construction of knowledge and the generalization process. The conflicts arose were removed effectively through the discussion. Alternative suggestions to the tasks were quite frequent, which brought multiple perspectives to the process.

Collaboration brings different roles to the teaching environment than those appear in the conventional teaching environment. This research indicated that conventional teaching was seemed to be not very effective in inserting the multiple perspectives that were initiated by the additional roles that students have in the collaborative small-group environment.

## **PRESCHOOL CHILDREN'S NUMERICAL THINKING IN PART-WHOLE SETTINGS**

Robert P. Hunting  
East Carolina University  
huntingr@mail.ecu.edu

A model of preschoolers' part-whole reasoning in the context of the first five numbers is proposed, based on data from previous research, and analyses of individual interviews with 14 preschool children (median age 3 years 10 months). A major cognitive tool at work in many of these children seemed to be an ability to visualize, not just static configurations, but sequences of actions, when outcomes of such actions were hidden from view. Problem situations where one or more items are added or removed from a small set appear to be potent experiences for the development of numerical part-whole reasoning, just as part-whole reasoning and integration operations serve as foundations for solving informal addition and subtraction problems.

Children younger than five years are able to deal with problem situations involving small quantities (Mix, Huttenlocher, & Levine, 2002). They are able to discriminate between sets of different numerosities in this range, have been found able to do so from the first months of life, are able to match small numerical sets across modalities, and are generally able to apprehend the numerosity of sets of items up to five without needing to count—a process known as subitizing. Preschoolers have intuitive ideas about addition and subtraction.

### **Conceptual Analysis of Preschoolers' Part-Whole Reasoning in the Context of Small Quantities**

#### **Qualitative Comparison Scheme**

A fundamental and innate ability to make gross comparative judgments of quantities is present in children from the earliest months. Perceptual strategies including length and density can be used in making judgments, although conservation of discontinuous quantities has not yet been achieved. Children know that observing items being added to a collection will have the effect of increasing the size of the collection. A cognitive structure for making these kinds of judgments possible has been called the protoquantitative increase/decrease schema (Resnick, 1989). Children in division situations involving the sharing of discrete items will partition a set with little apparent attention to equality of subsets.

#### **Quantitative Comparison Scheme – Up to 4**

Provided the number of items is perceptually accessible, and the number is in the subitizable range, young children are able to focus attention on quantitative relationships arising from physical transformations of a defined collection, and will use counting to enumerate small sets if needed. When counting behavior is observed, children

typically count each item deliberately; usually in response to the adult's question "how many?" However the last word response may not have cardinal meaning. Children in this stage are able to perform integration operations (Steffe, von Glasersfeld, Richards, & Cobb, 1983) on perceptually available material only, in the range 1-3.

### **Quantitative Comparison Scheme – Representational Stage**

Small sets can be represented internally using visual imagery when such sets are not perceptually accessible. Children in this stage are able to perform integration operations on representations of sets of 1-3 (visualized or figural), so that they are able to perform simple calculations mentally. For quantities beyond 3, perceptual material needs to be available. They also begin to communicate their ideas of quantity through use of finger patterns. Thus when asked how many items are hidden from view under a plastic cup, a child may respond by showing the number of fingers corresponding to the number thought to be hidden. Ability to anticipate the outcomes of transformations yet to be observed is limited.

### **Numerical Comparisons**

Children at this level are fluent in solving problems involving quantitative relationships within small collections. Prior experiences can be drawn upon to anticipate outcomes of transformations within small collections. These children can be said to have coordinated the logic of class inclusion with cardinal knowledge for the "intuitive" numbers (Piaget, 1941/1965). Thus they are aware that one is contained in two, but two is not contained in one, on up, to four or five. Development toward reversible part-whole operations is well advanced for problems involving small numbers. Emergence of symbolic activity does not depend on acquisition of conventional symbols, but such acquisition is well established and facilitative. In sharing situations, children use systematic many-to-one allocations, and check their resulting shares using counting methods.

A major cognitive tool at work in many children seemed to be an ability to visualize, not just static configurations, but sequences of actions, when outcomes of such actions were hidden from view. Success enumerating hidden items depended not only on an ability to visualize quantitative outcomes, but also keep track of two levels of outcome, unless perceptual feedback was needed. In children of this age, such visualizations are assumed to be predominantly spatial in nature. Can preschoolers make sets of 1-5 in their mind in the absence of physical material? Evidence from this study would suggest that this is so. How spatial representations of quantitative transformations evolve into numerical entities (if in fact this is universally the case) is yet to be explained. Children in this study were less successful enumerating more than 3 hidden bugs, supporting Starkey's (1992) observation of a discontinuity between 3 and 4 in children's numerical development. However, this discontinuity may just be relative to the ages of the children studied.

We learn that problem situations where one or two items are added to or removed from a small set appear to be potent experiences for the development of numerical part-whole reasoning, just as part-whole reasoning and integration operations serve as foundations for solving informal addition and subtraction problems. Part-whole reasoning and addition and subtraction operations in whole number contexts are reflexive cognitive skills. That is, facility with part-whole reasoning enables children to conceptualize, and be successful solvers, of addition and subtraction problems. Experience solving a variety of addition and subtraction problems enables development of part-whole reasoning, and a critical engine: progressive integration operations.

A continuing mystery requiring further study, is how numerical information is processed. A capacity to switch focus from individual items to a grouping or uniting of items, depending on the person's goals, seems fundamental. An integration operation has been proposed to explain how cardinal understandings are made possible. We are aware of the dynamics of part-whole reasoning where a subset is cut out from the whole while the whole set is kept in focus. We suppose that the logical operations of class inclusion are important here. The reverse situation, where a whole is rendered a part, by the conjoining of other items to make a new enlarged whole, prefigures the symbolic statements we know as addition of whole numbers.

## PROMOTING COLLABORATIVE LEARNING IN MATHEMATICS THROUGH STUDENT PRESENTATIONS: A STUDY BASED ON ACTION RESEARCH

Jane A. Lee  
University of Toronto/OISE  
janelee@oise.utoronto.ca

### Study Question

Does having teachers and students share part of the teaching responsibilities encourage and facilitate collaborative learning in the mathematics classroom?

### Purpose and Framework of Study

The background for this study is illustrated in the following teaching vignette:

*I have just returned a quiz my Calculus students have written. Instead of providing the correct solutions myself, it is my normal practice to have students who have scored full marks on specific questions take up the solutions with the class. A student heads to the front of the room and proceeds to explain correctly how she arrived at her solution. Her explanation is clear and so is her written solution on the board. After she takes her seat, another student raises his hand and asks me to explain the solution again. Other students vocalize their support for this request. I am careful to grant this request by giving the solution in exactly the same manner as the student who had originally given the solution, trying to use the same techniques and words that she has just used. When I am finished, the students that did not seem to understand the solution the first time all smile and nod their heads in understanding.*

This study is based on Action Research. A widely accepted working definition of Action Research is: “a form of self-reflective enquiry undertaken by participants (teachers, students or principals, for example) in social (including educational) situations in order to improve the rationality and justice of (a) their own social or educational practices, (b) their understanding of these practices, and (c) the situations (and institutions) in which these practices are carried out” (Carr & Kemmis, 1986). The research findings can be applied to a mathematics curriculum to encourage student presentations and promote collaborative learning.

### Methods of Inquiry and Data Sources

#### Research Setting

The study took place in two grade 13 Calculus courses that I teach this year at a secondary school in Toronto, Ontario, Canada. The school that I teach in is a termed school, so I have the same group of Calculus students for the entire 2001-2002 school year.

### Research Design

From November 2001 to December 2001, during the first term of the school year, the following three types of data were collected:

*Student evaluations of presentations made by their peers.* There were six student presentations made in each class and the entire class filled out evaluation forms after each presentation. On the evaluation forms, students had to identify themselves in order to ensure that the forms were taken seriously and properly filled out.

*Self-evaluations of presentations by students.* Each student filled out a presentation self-evaluation form after his or her presentation. The presentation self-evaluation form was identical to the one filled out by each student's peers, except that the former was titled "Self-Evaluation".

*Student questionnaires.* The entire class filled out questionnaires after the presentations. The questionnaire was designed to determine both a student's attitude and disposition towards math generally and towards presenting and learning from his or her peers specifically.

The presentation evaluations and the questionnaires both had a quantitative component and a qualitative component. In the presentation evaluations, made by the class, the presenter and myself, a presentation mark based on six components was scored out of a possible 30 points. The evaluations also asked for comments in terms of the strengths and weaknesses of the presentation.

In the questionnaire, a rating scale was used to determine a student's attitudes and disposition towards learning, especially in terms of their math education. As well, the questionnaire asked students for written responses in terms of how they felt their Calculus class was being taught.

The three types of data were collected and analyzed to determine connections that would help answer the study question. The data was examined quantitatively and qualitatively for correlation by comparing: (1) a presenter's current course grade compared with the quantitative scores from the peer evaluation, the teacher evaluation and the self-evaluation of the presentation; (2) the qualitative responses to the presentation evaluations in terms of the strengths and weaknesses of the presenter; (3) the summary of the quantitative scores on the questionnaire; and (4) the qualitative responses to the questionnaire.

### Results of Study

The findings from this Action Research study demonstrate that collaborative learning can be promoted through student presentations. This type of learning takes the emphasis off the teacher as the sole knowledge giver in the classroom. Through watching peer presentations, students realize that there are sources in the classroom other

than the teacher to whom they can turn to for help. Moreover, students discover that by making presentations they can better consolidate their knowledge of course content material and become better equipped to share that knowledge with their peers.

The findings on comparing a presenter's current course grade with his or her quantitative score from the peer evaluation illustrate that making a presentation will almost always improve a presenter's overall course grade. The presenter's peers benefit from the delivery of course content material and the presenter benefits by achieving a higher grade.

The qualitative responses to the presentation evaluations in terms of the strengths and weaknesses of the presenter demonstrate that when course content is delivered through peer presentations, students gain an appreciation for understanding different perspectives on the question. The degree to which a student benefits from his or her own presentation is determined by how strong a student he or she is in the subject matter. The above average students benefit by taking advantage of good presentations skills to increase course grade, while at the same time consolidating knowledge. Weak students benefit by being able to attain a presentation mark higher than their course grades achieved through quiz and test performance. The very strong students benefit by consolidating their deep understanding of the mathematical content, together with being able to practice their presentation skills. In addition, perhaps by undertaking qualitative tasks such as making presentations, all students will consolidate their knowledge and achieve higher marks on their quantitative evaluations. If this is the case, then making presentations may be even more beneficial for all students that participate.

The summary of the quantitative scores on the questionnaire illustrates that the consensus of the students is that presentations are beneficial to their understanding of the course material. The presenters benefit because they have to understand the subtle nuances of the topic. The presenter's peers benefit because they are exposed to another perspective on how to approach the topic. Although students generally agree that presentations are beneficial, there are still a number of students that are not reaping these benefits because they are not participating in the presentations. Further studies need to investigate how all students can be motivated to participate in the presentations so that they can benefit from them. The qualitative responses to the questionnaire also provide additional support for the suggestion that presentations help students better understand the content material. These responses shed light on why some students choose not to participate in the presentations. Students who feel that they are particularly weak in the content area and students who feel uncomfortable presenting in English are not participating.

Overall, the results of this Action Research study demonstrate that presentations are beneficial both to the presenters and to the presenters' peers. Almost all math students will see their overall course grade improve if they make presentations. In addi-

tion, making a presentation requires a student to fully understand the material that he or she presents. The presenter's peers have an opportunity to see how someone else tackles a question and to learn that their fellow students can be a source of knowledge for them. When students are encouraged to take responsibility for their own learning, collaborative learning through student presentations can be a powerful tool that helps everyone in the classroom.

### **Relationship of Study to the Goals of PME-NA**

This study based on Action Research addresses the major goals of PME-NA by attempting to link the research in collaborative learning to the practice of teaching mathematics in the classroom. This study is specifically based on linking research and practice, which is the theme of this year's PME-NA conference. Moreover, the study examines links between quantitative and qualitative evaluations and explores the motivations and rationales for students to participate in non-traditional learning activities within the mathematics classroom.

As a full-time secondary mathematics teacher and a part-time doctoral candidate, I appreciate the opportunity to make changes in my teaching practice based on the research and literature to which I am exposed in my own studies. I believe that by attempting to better understand the process by which students become accountable for their own learning, we can help ease the transition to post-secondary school. To be successful in post-secondary institutions, students require skills such as the ability to engage in collaborative learning and to take the initiative. If these skills are honed in secondary school, students will be better equipped to handle the challenges of post-secondary school. By supplementing research findings with actual classroom practices, we will be able to gain a better understanding of the psychological aspects of teaching and learning mathematics, which will have useful implications for the mathematics classroom.

**EMPHASIZING UNDERSTANDING IN MATHEMATICS CLASSROOMS**

Rodney E. McNair  
Delaware State University  
rmcnair@dsc.edu

What is the value of mathematics? While this question has been debated in the past, I would argue that current conditions in the world make one answer particularly reasonable. The value of mathematics is in the understanding that it provides about our physical and social environments. The science of mathematics may be beautiful and mental training may still be a valued outcome of mathematics instruction. However, the ability to use mathematics to develop understandings of things like global economic systems, technology, environmental science, music, art, and other things is the primary reason that most people need to know mathematics.

Many new curriculum materials emphasize the use of contexts in teaching and learning mathematics. In general, the primary role of the contexts in these materials is limited to serving as a catalyst for developing mathematical statements. Once a context has been translated into mathematical statements it is moved to the background so that emphasis can be placed on the mathematics to be learned. This makes some sense given that the full development of a context may divert attention from the mathematics to be learned. However, limiting the role of contexts in this way also limits the role of mathematics. Mathematics is used to compute an answer but is not used to form a frame for reasoning about and understanding the contexts.

**Understanding and Mathematics**

While there may be many different reasons to teach and learn mathematics, the primary use of mathematics is in developing understanding of our physical and social environments. I would argue that it is the use of mathematics to develop understanding that should influence the reasons and the ways that mathematics is taught in schools. This is consistent with Dewey's (1973) interpretation of the relationship between the learner and the curriculum. The attitudes, motives, and interests that have led to the development of mathematics can be found in the learner's attempts to understand his or her physical and social environments.

This focus on understanding in teaching and learning mathematics is also supported by the important role that mathematics plays in structuring our physical and social environment. As Skovsmose (1994) has argued, mathematics is absorbed into parts of our basic conceptual system and so assumes a power to format parts of our social environment. Geometric series and compound interest is an example of this formatting power. Lakoff and Núñez (2000) argued that our unconscious understanding of many mathematical concepts is supported by our ability to use metaphor to map the structure and meaning of everyday contexts onto these mathematics concepts. This subconscious connection between mathematics and our environment makes it all the

more reasonable to expect that mathematics would play a central role in shaping and understandings our environments.

It is the conscious use of mathematical metaphors as a resource for reasoning that motivates learning and developing mathematics. The use of metaphor allows us to extend our understanding of prior experience to new experiences that share structural similarities. Dewey (1973) argued that it is concepts that allow us to extend our understanding from one thing to another. Thus, by mathematical metaphor I mean the formal mathematical concepts that are the subject of school mathematics instruction. However, as Dewey also argued the meanings of these concepts are most fully realized when they are used to develop understandings of things that are relevant to the learner's current situation. These arguments elevate the role of contexts in mathematics teaching and learning from the background to the foreground.

### **A Note on Understanding**

There are many ways to understand a context. One may develop a spiritual understanding, a historic understanding, an economic understanding, or any combination of these and other kinds of understanding. The kind of understanding that is developed depends on the kinds of metaphors that are used and of course on the reasons one seeks the understanding in the first place. Thus, I am not arguing that mathematics is the only ways to understand a context but only that mathematics provides a particular kind of understanding that is often valuable.

There are four basic requirements that motivate a need for mathematical understanding. First, the learner must identify individual parts or components of an object or context. Second the learner must question the relationship between the parts that have been identified. A third requirement is that the learner questions the function of the object or context in a larger context. The final requirement is that the learner questions how the parts, the relationships, and the functions, change over time. It is in the effort to address these four aspects of an object or a context that the value of mathematics as a source for reasoning and understanding can be realized.

When questions concerning parts, relationships, function and temporal change are raised then mathematics variables, equations, operations, and systems become metaphors that we can use to understand many different physical and social contexts that share structural characteristics with these mathematics constructs. Thus, developing deep conceptual understanding of the structure of mathematics is key to being able to apply mathematics toward developing greater understanding of our physical and social environments. Also developing the ability to map meaning between mathematics and environmental structures should provide increased understanding of the mathematics concepts being used. It is within this framework that we can begin to investigate the fuller use of contexts in the teaching and learning of mathematics.

### Current Use of Contexts

An initial analysis of secondary mathematics and post-secondary mathematics texts has been conducted. I make no claim here that there is not some general goal of developing mathematics as a resource for understanding that is addressed in the texts that have been analyzed. My initial analysis was only concerned with the explicit use and treatment of contexts and understanding in the texts. The results reported here are preliminary but I believe characteristic of the results that the continued analysis will reveal. However, a further analysis that considers measures of more implicit uses of contexts in mathematics texts is ongoing.

Two evaluations of the mathematics texts are summarized here. How many different contexts are introduced in a typical unit or section and to what extent if any is a context discussed after the initial problem is solved? The first measure provides insight into how well the contexts are developed in the texts. The second measure determines the extent to which using the structure of mathematics concepts to understand the structural characteristics of the contexts is a goal.

General results indicate that current mathematics textbooks do not emphasize development of understanding of the contexts they introduce to support instruction. This is uniformly the case for traditional algebra and trigonometry textbooks. Each example and each exercise introduces a new context. Knowns and unknowns in the contexts are identified and represented with variables, an equation is developed and solved, and the context is not discussed any further. Mathematics is treated as the science of procedures for finding answers, contexts are treated as props for developing equations, and developing mathematics as a resource for reasoning about social and physical environments is not an explicit goal.

Curriculum materials such as Contemporary Mathematics in Context introduce fewer contexts but this is largely because there are fewer examples and exercises in the texts. The reduction in exercises is replaced by a stronger emphasis on developing contexts that are more meaningful to the students. More attention is given to understanding the process whereby social and physical contexts are converted into mathematical expressions and equations. This is accomplished largely by asking a series of related questions about the contexts, however, as with the more traditional texts, there is no explicit effort to relate the structure of the mathematics being used to solve the problem to the general structure of some aspect of the contexts. Mathematics is still largely limited to the computation of answers.

As stated these comments reflect my initial analysis of mathematics texts. Curriculum materials such as Contemporary Mathematics in Context and Data Driven Mathematics place a much stronger emphasis on the use of context and provide a learning environment that could support the development and use of mathematics as a reasoning tool to develop understanding of social and physical environments. A more thorough analysis of these texts that considers the implicit use of contexts may indicate that this is in fact a reasonable expectation.

While the results reported here are only preliminary they are sufficient to emphasize a need for increased attention on the ways that mathematics is used in curriculum materials. Treating mathematics as a one-dimensional computational device limits the students' understanding of mathematics and may adversely impact many students' motivation to learn mathematics. When our goal is to understand physical and social phenomena then mathematics is a tool for understanding. If we view history, chemistry, biology, engineering, or everyday life through a mathematical lens then what we develop is a better understanding. Conversely if we are not trying to understand anything then mathematics may be of little practical use beyond simple measurement and computation.

### Introduction

More than two decades and of research and experience supports the idea that computer and calculator technologies can have an important role to play in supporting and effecting student learning (Heid, 1988; Kaput, 1992; Kutzler, 1996; Papert, 1980; Waits and Demana, 1999). The development of Classroom Communication Systems (CCSs) is providing new possibilities for technologies to play a fundamental role in creating and supporting effective learning environments. The TI-Navigator, from Texas Instruments, is a wireless CCS and its advent brings the power and potential of CCSs into K-12 classrooms in a novel, flexible and mobile way. The pedagogical potential of CCS technology is still in its development stage but preliminary research suggests considerable benefits to active student participation in class and collaborative inquiry in the classroom (Abrahamson, Davidian & Lippai, 2000; Bransford, Brophy, & Williams, 2000; Davis, 2002; Dufresne, Gerace, Leonard, Mestre, & Wenk, 1996; Mestre, Gerace, Dufresne, & Leonard, 1997; Wenk, Dufresne, Gerace, Leonard, & Mestre, 1997). The present study is designed to illustrate the potential of CCSs in facilitating effective teaching and in creating effective learning environments.

### Theoretical Framework

Bransford, Brown, and Cocking (1999) developed a framework for designing effective learning environments. The design of such environments is based on principles which form the basis for a model of learning with specific implications for teaching called How People Learn (HPL). Consequent to these principles Bransford et al. propose that effective learning environments should be learner-centered, knowledge-centered, assessment-centered, and community-centered.

Aspects of a teacher taking a learner-centered approach include the extent to which the teacher uses questions, tasks, and activities to show existing conceptions that students bring to the classroom, and the extent to which teachers exert an appropriate amount of pressure on students to think through issues, establish positions, and commit to positions. A knowledge-centered approach manifests itself in a focus on

conceptual understanding, and the diagnosis and remedy of misconceptions. Assessment-centered instruction concentrates on formative assessment to provide feedback to students and to teachers on student conceptions. Finally, a community-centered approach is reflected in, for example, class discussion, peer interaction, and non-confrontational competition. (Bransford et al., 1999).

### **Description of the Technology**

From the mid-eighties to the present day Classroom Communication Systems (CCSs) have been a slowly evolving technology consisting of a network of palm-type devices or graphing calculators controlled by a central computer. CCSs consist of four main parts: (a) a computer which is operated by a teacher at the front of a classroom and which runs a software package; (b) an LCD panel, television, or other type of projection system which displays information; (c) student devices which may be calculators, computers, palm pilots or organizers; and (d) a network which connects student devices to the teacher's computer, interprets communication protocols, and sends tasks to and from students and the teacher. Using a CCS students can send in answers to multiple choice questions, send in alpha numeric answers to questions, send in lists of numbers based on measurements, participate in simulations controlling an on-screen icon or, so-called, turtle.

### **Methodology**

The participants in this study are ten high school mathematics and science teachers and their students. The teachers are experienced in teaching with graphics display calculator technology and were trained in the technical aspects of operating the TI-Navigator system as well as pedagogical techniques and possibilities available in a networked classroom. Before the training teachers were surveyed in open question format about their pedagogical practices and will be surveyed at the end of the school year about possible changes in their practice. A series of visits was undertaken to their classrooms where the TI-Navigator system is being used.

Shortly before the visits to classrooms teachers and students completed Likert-style surveys specifically designed to elicit their views of the extent to which TI-Navigator classrooms reflect the HPL model (i.e., the extent to which TI-Navigator classrooms are learner-centered, knowledge-centered, assessment-centered and community-centered). During the visits, formal observations of classes were made using the VaNTH Observation System (VOS) (Harris & Brophy, in progress). This system is designed to capture classroom interactions reflecting the HPL model. Interactions in the classroom are recorded and categorised as examples of one of the centerednesses. Responses to the Likert-style surveys were used as the basis of protocols for focus group interviews with students and individual teacher interviews. The interview protocols were designed, therefore, to gain further insight into the TI-Navigator classroom as exemplification of HPL effective learning environments.

### Conclusions

The role that CCS technology has to play in implementing HPL principles in the design of an effective learning environment centres on the free flow of information in the classroom: CCS technology gives teachers more information on what students are thinking, gives students more information on what other students are thinking, gives students more information on their progress, and supports sharing of information to facilitate collaborative learning. The accumulation of effects of the use of the TI-Navigator on student feeling, motivation, behaviour and classroom dynamics suggest that the TI-Navigator can have a positive influence on student learning. These findings illustrate the potential of CCSs in facilitating effective teaching and in creating effective learning environments however, more research is needed to develop and refine these initial understandings.

**WHAT DO STUDENTS ATTEND TO? OBSERVING STUDENTS' MATHEMATICAL THINKING-IN-ACTION**

Immaculate Namukasa  
University of Alberta  
namukasa@ualberta.ca

In this report, I discuss some preliminary findings from an ongoing research project. From an enactivist inquiry, the research study seeks for an understanding of the nature of students' mathematical thinking: what students attend to in mathematical tasks and what is the dynamics of this attention. The study involved 7 students who were engaged in extra curricular mathematical tasks. Data included observations and video recordings. Manipulative materials, symbolic records, embodied problems posed and the other students' understanding are seen to influence what students attend to. Also, particular forms of utterances and written work are seen to indicate differences and shifts in what students bring forth from the tasks.

In recent studies on mathematical thinking researchers acknowledge that exposure to well presented mathematical concepts does not guarantee that students will come to think mathematically. In addition to psychological and mathematical influences, researchers recognize experiential, social-cultural and institutional influences on students' learning (Kieren, 2000; Lave & Wenger, 1991; von Glasersfeld, 1995). In order to understand why students fail to learn seemingly well-taught concepts some researchers have studied discrepancies between students' idiosyncratic conceptions and images, and the "standard" mathematical concepts and definitions. However observer constructs such as these discrepancies, cognitive obstacles or conflicts and children's misconceptions that are based on the acquisition model of learning inadequately explain the complexity of learning (Davis & Sumara, 2000; Sfard, 2001). This research that is based on enactivist inquiry aims at understanding students' mathematical thinking by studying what students attend to and what problems students pose as they engage in mathematical tasks. The study relates to studies that view mathematical knowing as coming to see what is mathematically significant, such as Mason (1989) and Sfard (2001). The study, nonetheless, emphasizes that perception is prejudiced, and that it holistically includes listening, imagining, touching, expressing etc. in addition to seeing. That is, perception is inseparable from conception.

The ongoing research has so far involved seven junior high students in extra curricular sessions. In each session paired students engaged in non-routine, variable entry mathematical tasks. I observed as well as participated in an interventionist teacher mode, by offering ongoing prompts (Towers, 2001). At the end of each session, in a conversational interview, I encouraged students to talk about their actions and interactions. The analysis and interpretation in this study involves gaining some insights into the embodied and co-emergent nature of students' mathematical thinking and, consequently, how it is occasioned.

From the enactivist perspective, cognition is embodied—it is all-at-once mathematical, evolutionary, psychological, biological, socio-cultural and institutional (Kieren, 2000). Cognition is viewed as perceptually guided actions; it is an act of specifying, of in-forming the relevant features of the environment (Simm, 1998). In embodied cognition, our actions and what we attend to are taken to be inseparable (Varela, Thompson & Rosch, 1991). Thus the nature of students' mathematical thinking and actions (conceptions) and what they attend to (perceptions) as they engage in mathematical activities are co-implicative. What a learner may attend to is not only a feature of the "object" of attention. It is also determined by the structure of the learner—the biological, social and historical *readiness* (to use Bruner's term) to attend—and the environment, which includes other learners and the teacher. Unfortunately, in analyzing students' difficulties in understanding concepts, say of fractions or of limit, researchers have hardly focused beyond the structural properties of mathematical tasks. Bruner (1996) remarks that what we attend to is one of the many possible worlds. There is need to hermeneutically study how students' situational factors and structures come to bear as students bring forth mathematical worlds during mathematical activity. Transcripts of the sessions together with students' written work were analyzed. In the analyses, I paid close attention to students' actions and interactions: What they said and how they said it—voice inflection, body language, metaphors and analogies; and what they wrote and how they wrote it—the representations, visualizations, and form and content of the symbolic records. In an attempt to develop ways of observing mathematical thinking-in-action the interpretations sought to explore the selective nature of students' perception that filters the relevant mathematical meaning from what is taught.

Three themes emerged from the data from the project and from a related classroom research. First, what students attend to seemed to be intertwined with: the manipulative materials that the students worked with, the symbolic records that the students kept and the other students' understanding. On a moment-to-moment basis the concrete materials and symbolic records played an evocative role as sites for mathematical interpretations besides being re-presentations of already formulated thoughts and actions. As presentations the materials and written records opened up spaces for learners to articulate the at once unformulated. Often students who worked collaboratively appeared to be sharing objects of attention to the extent that most shifts in attention were collective and seamless. Second, subtle variations in the use of concrete materials at times gradually called forth different thoughts and actions. For instance students assembled fraction kits<sup>1</sup> by seeing the strips as discrete objects rather than as proportions of a whole piece of paper. This way, even when they got the same answer, the students over played the ratio aspect—number of pieces—at the expense of the quantity aspect—size or length of pieces—of fractions. In another task the students manipulated the dominoes and chips to find out numbers that could be arranged as a string of consecutive positive integers. As they continued to make sense of the

numbers, they posed different problems and their focus shifted from the geometrical shapes of the numbers to the pattern of the first digit in the arrangements. Third, loud, animated and proactive utterances, and the episodic nature of students' writing at most times indicated shifts in attention to what was mathematically significant. This relation might suggest that emotions are braided with thinking-in-action.

As the research study proceeds, I hope to pursue the themes further. From ecological perspectives, mathematics teaching might have to do with prompting students to notice certain aspects of their worlds and to interpret those elements in particular ways (Davis, Sumara, & Luce-Kapler, 2000; Mason, 1989). In which case the teacher's responsibility is to attend to the learners (so as to attend with the learners) as they make sense of their mathematical worlds. The exploration of how students interpret mathematical situations might not only offer to researchers and to teachers developed ways of observing what students attend to, but also open up possibilities "to attend with" the students so as to enhance mathematical thinking.

Alejandro Rivera  
Intermediate School 195  
arivera666@aol.com

This paper is one of two that focus on the use of mathematical inscriptions. Both papers give case studies of how groups of learners grapple with important concepts in surprising ways. In each case, despite large differences in age and setting, understanding what the learners *write and draw* supports key steps toward understanding how they learn. In this paper, we consider data from an eighth-grade classroom in a multicultural urban school. We follow a series of three inscriptions, tracing carefully how they are built and used.

The work presented here is part of a larger investigation about the building and communication of mathematical ideas, which continues a sequence of investigations by the first two authors (Speiser & Walter, 1994, 1996, 1997, 2000). We chose here to write about a multiracial, multicultural urban classroom to investigate a particular hypothesis: the need to focus on communication might *facilitate* building collective discourse about models, proofs, strategies, explanations, and justifications. In this note we concentrate on how five students in this classroom built and used three *inscriptions*, first to justify a particular solution, and then to help present their thinking to the class.

For us, a representation—for example an inscription—is a *presentation*, perhaps to oneself as part of an ongoing thought, or perhaps to others as part of an emerging discourse. We analyze inscriptions from two closely related viewpoints: (1) to more clearly understand how learners build both personal and socially negotiated meanings, and (2) to document, based on these meanings, the kinds of reasoning, especially the kinds of argument and justification, that the learners use, share, and debate. We report data from a single two-hour classroom session, led by the fourth author (Alejandro Rivera) in Intermediate School 195. Located in West Harlem, IS 195 is an urban, overpopulated, multicultural school, whose students include many recent immigrants. Thirty-six students participated in the session we report, on March 30, 2001. They came from the Dominican Republic, Mexico, Ecuador, Yemen, Ivory Coast, Senegal, Guinea, Guinea Bissau, and Mali. In this session, students spoke Spanish, French,

Arabic, and at least three indigenous African languages in addition to the English they were learning. To communicate, students and teacher often had to translate through a chain of several languages. We videotaped the session with one digital camera, and photocopied student written work. The task reported here (Figure 1) was adapted from *Mathematics in Context* (1997): "Four sub sandwiches will be shared among 6 students. Draw lines to show how the students can divide the subs so that each student gets the same amount of sandwich. What fraction of a sandwich does each student get?"

Figure 1. The submarines as shown in the students' task.

In their initial exploration, graphic and numerical inscriptions are seen to emerge together in the course of animated conversation, first to refute a proposed but incorrect solution, then to justify and later help communicate a more grounded and also correct response. The first proposed solution of 1.5 emerged by dividing six students by four sandwiches. Abibatou, reading the problem statement, insisted, "The problem says, uh, show the graph... Draw, draw lines, draw lines." On her own, she drew lines (Figure 2, left) to connect one student with 1.5 sandwiches and did not finish the inscription, very likely because six iterations of the segment representing 1.5 would obviously go beyond 4.

Five minutes later, the rest of the group still did not seem ready to dismiss the proposed solution of 1.5, which Abibatou rejected earlier. As shown below, Abibatou linked a numerical inscription (a calculation) to her graphic representation by adding 1.5 six times (see Figure 2, middle). She then used her numerical inscription to refute the proposed solution 1.5. Writing emphatically, she explained, "Ya 1, ... 1 point 5, 1.5, 1.5, 1.5, 1.5, 1.5. See, see that, that's not equal to four sandwiches." Indeed, the six ones in the left column of her written calculation visibly (note, too, her repeated use of "see") gives 6. In our view, the inscription, especially its iterated 1s, allows Abibatou to reduce her refutation to the simple counting of six 1s. We can view the inscribed calculation, therefore, in two ways: in the background as the addition of six decimals, and in the foreground as the counting of six 1s.

The transcript indicates that Abibatou was aware that the correct solution was 4 divided by 6. She used a revised form (Figure 2, right) of her first graphic inscription to show her group (and later the class) that this solution was correct. In other words, use of a new inscription helped to ground, this time, a proof. Her proof was based on multiplying rather than on counting. Aniuska now invites Abibatou to explain her argument.

The need to build instruction based on learners' prior experience and current thinking, in evidence above, hardly seems to need discussion. How to *meet* that need, however, has been the subject of considerable debate. Impacted urban classrooms surely stand to benefit from close attention by researchers, given the challenges, inequities and needs clearly in evidence. In the longer study, this particular analysis contributes evidence that students in this classroom used a variety of quite sophisticated strategies, to discover and construct solutions and to anchor proofs and explanations, first within their groups and then in presentations to the class. Based on these analyses, we can assess our main hypothesis about the function of communication. If strong emphasis on communicating *reasoning* can help students to build important mathematical understanding here, in this impacted urban setting, then, given appropriate conditions and sufficient time, they could help to foster students' learning anywhere.

**JAPANESE CHILDREN'S UNDERSTANDING OF TEN AS A UNIT**

Tad Watanabe  
Pennsylvania State University  
txw17@psu.edu

Fumi Ginshima  
University of Kanazawa  
ginshima@ed.kanazawa-u.ac.jp

An exploratory study was conducted to investigate Japanese children's (ages 5.5 to 7.3) understanding of ten as a unit, using the framework developed by Steffe and his colleagues. We will discuss insights gained on Japanese children's understanding of ten and possible influence of the language structure.

**Introduction**

International studies, both large and small scale, have shown that students from Far Eastern countries such as Japan, Korea and China consistently outperformed their counterparts from the West. Some researchers have noted that the number words in those countries reflected the base-10 numeration system very closely, and such language structure may be a contributing factor for their superior performance. For example, Fuson & Kwon (1992) discussed how Korean language structure may have helped Korean children to develop efficient methods for simple addition and subtraction problems. Miura & Okamoto (1989) suggested that the Japanese children's cognitive representation of numbers positively affected their understanding of place values. Some of these researchers speculated that the number word structures in Far Eastern languages may have contributed to their children's performance.

On the other hand, research by Steffe and his colleagues suggest children's concepts of units play a central role in their understanding of numbers (Cobb & Wheatley, 1988; Steffe & Cobb, 1988; Steffe, von Glasersfeld, Richards, & Cobb, 1983). However, there has been no study that investigated Asian children's understanding of ten as a unit. Thus, a small scale, exploratory study was conducted to analyze Japanese young children's concepts of ten.

**Research Questions**

The current study has two major purposes. First, the study explored whether or not the theoretical framework proposed by Steffe and his colleagues in their work with children in the United States might be useful in analyzing Japanese children's understanding of numbers. The second purpose is to gain additional insights into Japanese children's understanding of numbers.

**Theoretical Framework**

In order to truly understand our number system, children must be able to conceive ten as not only a collection of ten ones but also an entity in itself. Moreover, they must be able to count and increment by tens. Thus, children must understand ten as an iterable unit to make sense of base-10 numeration system. Steffe and his colleagues' work

with children in the United States revealed that children's number concepts development was heavily influenced by units with which children can work. In our base-10 numeration system, the ability to work with ten as a unit plays an important conceptual step in young children's number concept development. In particular, Steffe & Cobb (1988) hypothesized five unit types of ten children construct: (1) numerical composite, (2) abstract composite, (3) ten more, (4) repeatable, and (5) iterable.

Of these three, numerical composite, abstract composite and iterable unit of ten appear to form significant demarcation points in children's understanding of ten as a unit. Ten as a numerical composite unit means that children consider ten as simply a collection of ten units but not *one* unit of ten. In that regard, ten is not different from any other number. Ten as an abstract composite unit, on the other hand, means that children can consider ten as a collection of ten units and one ten *simultaneously*. However, children with abstract composite unit of ten rely on the availability of suitable materials to re-present ten as a unit. Thus, they are still unable to anticipate the results of counting activity nor counting by ten does not signify incrementing by ten more ones. When children can finally free themselves from the need for materials to re-present unit of ten, they are said to have constructed ten as an iterable unit. In this study, we focused our analysis on these three types of ten as a unit.

### Methodology

A convenient sample of 12 Kindergarteners, ages ranging from 5 years and 5 months to 6 years and 3 months, and 12 first graders, ages from 6 years and 8 months to 7 years and 3 months, participated in this study. These students attended the Kindergarten and the Elementary School affiliated with the College of Education of a national university in Japan. Therefore, these students are by no means a representative sample of Japanese children.

Each child was individually interviewed. There were four types of interview questions for children in both age groups. These tasks were adopted from Steffe and his colleagues' work and involved individual counting squares and ten-strips (rectangular strips on which 10 squares were marked off). These interviews were semi-structured in that there were a set of common questions for each age group. However, based on children's response, the interviewer asked additional questions, and or or altered the size of numbers. Each interview took approximately 20 minutes.

Counting (CT) tasks introduced children to the materials. It also investigated how children count and how far they could count. In Screened Tasks Sum (STS), children were shown several counters/ten strips, and they were asked how many counters they see. The interviewer then informed children how many counters were hidden below the screen and asked if they could find out how many counters there were in all. In Screen Tasks Missing Addend (STMA), the set up was similar. The difference was that, instead of informing children the number of hidden counters, the interviewer told children how many counters there were altogether. Children were then asked to figure

out how many counters were hidden. Finally Tens Task (TT), children were asked to find the total number of counters as counters were laid in front of them. See Table 1 for the numbers used in the standard tasks for each grade.

**Table 1.** Numbers Used in the Standard Questions in Each Grade.

| Task | Kindergarten  | Grade 1   |
|------|---|---|
| CT   | 3; 7; 10; "10"; 14 ("10" + 4);<br>20 ("10" + "10")                        | 7; 10; 14 ("10" + 4);<br>20 ("10" + "10")   |
| STS  | [20] + 3;<br>[5] + 10;<br>[30] + 20                                       | [7] + 11; [31] + 8;<br>[23] + 15; [28] + 7;<br>[8] + 43; [36] + 29                              |
| STMA | [ ] + 5 = 25;<br>[ ] + 10 = 7;<br>[ ] + 30 = 50                           | [ ] + 5 = 25; [ ] + 10 = 17;<br>[ ] + 30 = 50;<br>[ ] + 7 = 35; [ ] + 43 = 51;<br>[ ] + 18 = 43 |
| TT   | 6; "10"; 3; "10"; "10"; 4; "10";<br>"10"; "10"; 2; 5; "10"; "10"; "10"; 2 | 6; "10"; 3; "10"; "10"; 4; "10";<br>"10"; "10"; 2; 5; "10"; "10";<br>"10"; 2                    |

Note. "10" in CT and TT indicates a ten strip. Numbers inside brackets in STS and STMA indicate the number of counters hidden underneath the screen. The symbols, "+" and "=" are used for our convenience. Formal addition language was not used by the interviewers.

### Data Analysis

All interviews were videotaped then transcribed. We used both videotapes and transcripts in their analysis of the data. In CT and STS, children's counting activities were noted. In particular, we asked, "Can children produce the decade number sequence (10, 20, 30...) correctly?" "Can they count on, and if so, can they count on from any number, or from a decade number?" "Can they coordinate the decade number sequence and the standard number word sequence (1, 2, 3...)?" In STMA and TT, we focused on children's use of ten as a unit. In particular, we were interested in how children counted ten strips.

### Presentation

During our presentation, we will present the summary of our analyses. We will then share with the audience our assessment of the usefulness of Steffe et al.'s framework in analyzing Japanese children's understanding of ten as a unit. We will also

share insights gained from this study on Japanese children's understanding of ten as a unit as well as any possible influence of language structures.

## IN THEIR OWN WORDS: TEACHER AND STUDENT REFLECTIONS ON A WIRELESS NETWORK OF HANDHELDS

Sarah M. Davis  
University of Texas & Texas Instruments  
Davis.s@mail.utexas.edu & sdavis@ti.com

This paper illustrates areas of impact on education (anonymity, confidence, teaching options, use of data and engagement) by uses of a classroom network of handheld devices. A series of interviews was done with a group of students, and their teacher. This group used the network on a daily basis for the entire 2001-2002 school year. Excerpts from those interviews help to tell the story of this technology.

### Reflections

In the networked classroom, students can submit answers to be considered by the class without their identity being associated with that information. Anonymity facilitates the ability to explore answers in a non-threatening way, freed from *who* sent in an answer; students are able to explore *what* the answer is.

Teacher: It just promotes a lot of discussion and everybody's free to discuss it because kids can be criticizing an equation that they themselves wrote and nobody would know.

Students identify with their response, icon, data, etc. that shows up in the group display. With time, this representation of self in the group space can give the students a sense of how they are doing relative to the class as a whole.

Interviewer: Does that, in the other classes where you don't know how other people are doing (Student 12: Right), you don't know if you're the only one (Student 12: Right), does that raise your anxiety level any...?

Student 12: Yeah it's scary, because I think I'm the only one...I'm looking at my test, I think I'm the only one who got a 60 or whatever. And the couple of kids around me I'll know what they got but then I have no idea how anyone else is doing, because it's all privately done. Not that I need to know their test grades, but I'd like to know, how I stand. Am I the only one who needs help? And then you feel embarrassed to be the one raising your hand all the time, be the one staying after class because you think you're the only one. So, here, it's a lot more comfortable. You're not embarrassed in front of the other kids.

The ability to gather responses on all questions from all students gives important knowledge to the teacher. That knowledge then gives the teacher options for how to proceed in class.

Teacher: It's great to know, where the kids are, actually it's not always great because sometimes it's pretty depressing to see where the kids are. There was something I did this year in one of my classes and I asked if there were any - I thought I had done a fine job - I asked if there were any questions, nobody had any questions and I just had an inkling, And I said okay well log on and lets check. And I believe two kids got it right so obviously they didn't have a clue what they were doing and I went back and re-taught.

An interface, which scaffolds the teacher and students' navigation of the device, and the ease with which the network moves and shares students' data, makes data intensive; standards based activities more accessible to teachers.

Interviewer: In the class what do you think you can do now that you really couldn't do before?

Student 7: I'd say with the labs, the labs that we do. I don't think we would be able to do them as easy and as quickly as we can now. Like the Music Lab and everything that we just did. It just goes so much quicker. Instead of having "Okay, copy this from here..." you know it's just "Okay it's in the calculator, send it," everybody gets it, it's a lot quicker and easier.

Not raising your hand or avoiding eye contact no longer lets a student off the hook for participation. The network enables all students to be more engaged in the classroom.

Student 14: Well, with collecting since she collects the data from everyone, she checks, it's an easier way for her to check homework without having to single anyone out and it's also, the whole class is doing the work now and learning it and no one can really get away with just faking any of the work.

## TRINITY PARADIGM OF INTELLIGENCE

Masoud Ghaffari & Roland Pourdavood  
Cleveland State University  
mghaffari@worldnet.att.net

The intention of this research report is to unfold a unified concept or the essence of human intelligence. What is intelligence? This study is grounded in the transpersonal phenomenological methods of Braud and Anderson (1998). We believe these methods are viable approaches for exploring individual's experience of intelligence and intellectual potential. Our interviews consisted of three parts. The first part was a personal story. The second part dealt with an example of an intelligent person and elaboration on that idea. And, the third part was elaborations on the role of human intelligence in achieving a life purpose as perceived by each of the participants.

After analysis of the transcripts and data reduction, three main categories emerged: (1) Intra-personal, (2) Interpersonal, and (3) Transpersonal. Intra-personal attributes are within the realm of a person. Such a personal boundary encases and connects those elements that interact at the cellular, tissue, organ, and finally whole body function. The second category is Interpersonal attributes. These represent interdependence and interconnectivity between individual and others/environment. The third category that emerged was transpersonal. Interconnection of one to oneself and then to friends, family, community, society, environment, and ecosystem through a realization of a sense of wholeness which enables one the freedom to get closer and ultimately unite with her/his spiritual essence.

Although each one of these attributes may look different at first glance, they all share a common essence of interconnection or interdependence. For example, "analytic ability" and "mathematical ability" denote one's ability to compare and contrast qualities and quantities of events, situations, numbers, equations, occurrences, and data. In the case of "information processing," it denotes one's ability to gather and perceive information, data, or input, process, and compare them with what is already stored in memory, and finally transform them to an output. Again, the essence of such processing is the ability to interconnect input, throughput, and output. Human intelligence is where all our thinking, acting, and feeling originate. Therefore, the holistic theory of TPI has significant implication in mathematics education and mathematical literacy. The goal of many research and implementation efforts in mathematics education has been to promote learning with understanding. Helping our students to realize who they are, emphasizing the process of "human-becoming," with interdependence being our main intention, empowers our students to place mathematics into meaningful context in their daily living. This way they are endowed with more creative ways of problem locating and problem solving. In addition, students become more confident in their abilities to recognize patterns and relationship among patterns. Also, this

approach helps them to become more intuitive thinkers, considering alternative strategies, and discovering/inventing more intelligent solutions.

## **PICTURES OF CALCULUS KNOWLEDGE NETWORKS: DATA AND SOFTWARE**

Eric Hsu  
San Francisco State  
erichsu@math.sfsu.edu

This talk describes our findings from a study on the conceptual development of calculus students and emphasizes our attempts to construct visual and schematic diagrams of student understanding and the connectedness of their ideas. In particular, we hope that by introducing graphical and computer-aided methods, we can begin to study student spontaneous reasoning as an emergent phenomenon in its own context and not merely in relation to more official or formal expectations. We will display graphical representations of mathematical problem solving and introduce the software tools used to create them. We will need board space for paper displays and, if possible, a laptop projector.

The importance of the connectivity of student mathematical understanding has been a strong theme in recent work of such varied authors as Li-Ping Ma, Steve Monk and David Tall. However, when trying to qualitatively analyze the richness and connectivity of student knowledge, as either a teacher or a researcher, it is highly tempting to do so without interpreting student knowledge as either competent or deficient with respect to a selection of possible official mental organizations (e.g., the conventional metaphors of Cartesian graphical representations or function analysis). Indeed, one essential difficulty is that avoiding such preconceived structures requires gaining access to student's forming and dynamic knowledge networks, in which ideas may be connected tenuously and inconsistently.

In our study, we analyze student understanding of limit and covariational reasoning in terms of their facility with different metaphorical contexts and we attempt to characterize and diagram the connectivity of student ideas using a combination of qualitative analysis and computer-aided text and network analysis. We introduce these techniques in an attempt to acknowledge and capture the role of informal reasoning in the development of rich connected understanding, a topic on which there is much lively disagreement (for instance between neo-Piagetian APOS theorists who consider informal reasoning to be a temporary scaffold, to Vygotskians who assign a central dialectical role for intuitive reasoning, to Lakoff and Nunez who posit that mathematical reasoning is a series of metaphorical abstractions carrying structure from more basic notions which are all eventually rooted in the most basic embodied experiences).

We believe that the analyses presented are promising first steps towards an analysis of student use of language in reasoning that give evocative approximations of these fleeting but essential mental connections. Our analysis amplifies a careful semantic analysis of local relations between mathematical ideas of students by using computers

to analyze the larger patterns that emerge from such fine-scaled analysis, and indeed to constructing visual representations of these larger patterns.

The study was performed during the academic year 2000-2001, and had both a large-scale and fine-scale component. We gathered data from a class of 120 students enrolled in a first year calculus course at a major southwestern public university. We conducted task-based interviews with 14 students. Each student was interviewed and audio taped three times during the year for about an hour per session.

## **THE NATURE AND ROLE OF TEACHER INTERVENTION WITH RESPECT TO DISCOURSE IN THE MIDDLE SCHOOL MATHEMATICS CLASS**

Mary P. Truxaw, Thomas C. DeFranco, & Jean M. McGivney-Burelle  
University of Connecticut  
mary.truxaw@uconn.edu

Verbal discourse, defined as, “purposeful talk on a mathematics subject in which there are genuine contributions and interaction” (Pirie & Schwarzenberger, 1988, p. 460), is recognized by the National Council of Teachers of Mathematics [NCTM] and by social-constructivist theorists as providing potentially important scaffolding to the learning-teaching process (Cobb, Yackel, & Wood, 1992; NCTM, 2000; Vygotsky, 2002). Professional and theoretical literature points to the importance of the teacher’s role in helping to make classroom discourse meaningful, but also notes that the teacher’s voice has been underrepresented (Chazan & Ball, 1995; Lampert & Blunk, 1998; NCTM, 2000). The teacher’s role is a critical one in the orchestration of discourse in the mathematics classroom (Chazan & Ball, 1995).

The most common form of classroom discourse is ‘triadic dialogue’ that includes IRE (initiation, response, evaluation) or IRF (initiation, response, follow-up) (Cazden, 1988; Knuth & Peressini, 2001). Lotman (1988) categorized discourse as univocal (one-way transmission of knowledge) and dialogic (dialogue with its aim being the construction of meaning) (cited in Knuth & Peressini, 2001). Teachers’ interventions within the IRE/IRF structure have been shown to play a significant role in whether the discourse tended more toward dialogic or more toward univocal (Wells, 1999). Knuth and Peressini (2001) presented observations from mathematics classes that supported the importance of the teacher’s role in the development of dialogic discourse, but did not present a detailed linguistic analysis of the IRE/IRF structure. Wells (1999) presented an analysis of classroom discourse supported by linguistic theory, but did not examine discourse within mathematics classes.

This study applied sociolinguistic tools to examine the teacher’s role in discourse within mathematics classes, focusing on the teacher’s interventions within the IRE/IRF structure. Two middle school mathematics teachers noted for their use of instructional programs aligned with the NCTM Standards were interviewed and observed. Classroom observations were audiotaped, videotaped, and transcribed. Pre- and post-observation interviews provided background for understanding the teachers’ perspectives about classroom discourse. The transcribed classroom observations were coded, focusing on “moves” (Wells, 1999) that were found to be critical in distinguishing dialogic and univocal discourse.

The results indicated that the teachers in the study valued classroom discourse as noted in the NCTM Standards. Although discourse was evident throughout the class-

room observations, it was predominately univocal in nature, i.e., the teachers conveyed meaning to the students, but the dialogue indicated that the students generally did not generate meaning for themselves. There were times when the discourse tended toward dialogic, but the classroom discourse was rarely categorized as truly dialogic. Future studies will search for themes that explore the tendency toward univocal discourse in mathematics classes and the conditions that lend themselves to the appropriate use of dialogic and univocal discourse in effective mathematics instruction.

## **STUDENTS' UNDERSTANDING OF SOUND WAVES AND TRIGONOMETRIC REASONING IN A PROJECT-ENHANCED ENVIRONMENT**

Jennifer Wilhelm  
Texas Tech University  
Jennifer.Wilhelm@ttu.edu

Jere Confrey  
University of Texas at Austin  
Jere@mail.utexas.edu

This paper reports a study that examines gains made by students participating in a project-enhanced, Industrial Electronics (IE) high school course unit that was designed to promote the developmental understanding of sound waves and trigonometric reasoning. The unit was designed to foster common content learning (via benchmark activities) by all students in the class, and to help students gain a deeper conceptual understanding of a specific topic through group project work.

Benchmark activities included student participation in the analysis of motion and musical waveforms using probeware and student exploration of wave phenomena using wave simulation software. Other activities were also used to bridge the ideas of triangle trigonometric ratios to the graphs of sinusoidal curves, which lead to the understanding of frequency, period, amplitude, and wavelength concepts.

The group project work was initiated by asking students to investigate the question, "What salient features are required in order to reproduce sound?" After preliminary student research on this question, students were asked to generate and then investigate their own driving question, which was derived from the original research question. The three groups emerged with projects of radio waves, hearing implants, and the sound quality of compact discs.

Both quantitative and qualitative data were collected in order to assess student gains in understanding of sound waves and trigonometry. Quantitative data was comprised of pre-and post-tests while qualitative data involved videotaped clinical student interviews, classroom observations, and videotaped classroom activities of the High School Industrial Electronics classroom. Special focus was placed on student use of benchmark activities to assist their project work, and how project work facilitated benchmark lesson understanding.

Two students clearly showed that group project work, enacted in conjunction with benchmark activities, enabled understanding of course content due to ability to connect and relate in a bi-directional manner their individual group project work with the benchmark activities. One student, Evan, from the Radio Waves group obtained the deepest understanding of superposition when he connected superposition ideas obtained from his research on radio waves with superposition ideas visited during benchmark activities. Evan made the realization that a radio wave is formed through superposition of a modulating wave (he called sound wave) and a carrier wave. This

student went on to score perfectly on all superposition problems on the post-test, and obtained the largest gain score on these superposition test items.

The second student was a member of the hearing implants group. While examining normal modes on a simulated string, he verbally described how the normal mode was like a vibrating eardrum. Later during a post-implementation interview he explained how he could find the period of a given graph by relating it to the first harmonic (fundamental mode) on a string, which he had also previously related to a vibrating eardrum. During the post-interview, this student scored perfectly on questions involved with finding the period of a given waveform, and he made the largest gain score going from the pre- to post-trigonometry test.

This paper provides insight into future ways to design a project-enhanced classroom that ensures opportunity for students to learn specific content goals of a course, while simultaneously becoming “experts” of their own research topics. Final results showed that students who had a driving research focus, thought about and connected their group project work with benchmark activities, made the greatest gains in conceptual understanding. This project implementation design demonstrated the need for both the benchmark and group project implementation features.

## **History and Aims of the PME Group**

PME came into existence at the Third International Congress on Mathematical Education (ICME 3) held in Karlsruhe, Germany in 1976. It is affiliated with the International Commission for Mathematical Instruction.

The major goals of the International Group and the North American Chapter are:

1. To promote international contacts and the exchange of scientific information in the psychology of mathematics education.
2. To promote and stimulate interdisciplinary research in the aforesaid area with the cooperation of psychologists, mathematicians and mathematics educators.
3. To further a deeper and better understanding of the psychological aspects of teaching and learning mathematics and the implementation thereof.

## Preface

It is with great pleasure that we at the University of Georgia host the 24<sup>th</sup> annual meeting of PME-NA as we also hosted the 4<sup>th</sup> annual PME-NA meeting exactly 20 years ago in 1982. A quick glance at the differences between then and now shows how the field has grown and changed: The proceedings that year were about 250 pages long, and there were 34 papers presented in 7 topic areas. This year the proceedings will be nearly 2000 pages long with over 200 presentations in 15 topic areas. Despite the growth of the field and the organization, the hallmarks of collegiality and open intellectual exchange remain.

The theme of this year's conference is *Linking Research and Practice*. The theme is intended to highlight the interplay between the ways that research is used in practice and the ways that research grows out of practice. The invited plenary speakers were asked to address the theme in their areas of expertise by challenging the audience to think critically about the research we do—the questions we ask, the methods we use, the contexts in which we do research, the people with whom we do research, how we communicate the results of our research, etc. We hope that those in attendance as well as those who will read these papers in years to come will be stimulated to think deeply about our roles as researchers and consumers of research.

We received over 250 proposals for sessions at PME-NA and are grateful for the work of the many reviewers who helped shape the program. We undertook only structural editing (format and references) on the final papers so as to leave intact the integrity of the authors' work.

We wish to express our appreciation to the many people at the University of Georgia who have made these volumes and this conference a possibility, including, but not limited to, Patricia S. Wilson, Margaret Caufield, Elizabeth Platt, Salli Park, Bernice Peters, Teresa Banker, Nancy Williams, Joseph Allen, Brian Wynne, and all of the faculty and graduate students in the Department of Mathematics Education.

*The Editors*

**PREPARING PROSPECTIVE ELEMENTARY TEACHERS TO FOSTER  
CONCEPTUALLY BASED MATHEMATICAL UNDERSTANDINGS:  
A STUDY INVESTIGATING CHANGE IN PROSPECTIVE  
TEACHERS' CONCEPTIONS RELATED TO MATHE-  
MATICS TEACHING AND LEARNING**

Babette M. Benken  
Oakland University  
benken@oakland.edu

Nancy Brown  
Oakland University  
n2brown@oakland.edu

This study reports first year findings from a multi-year research project that examines changes in prospective elementary teachers' conceptions related to conceptually based mathematics teaching and learning. This study is the result of a *design experiment* (Brown, 1992) advanced between traditionally distinct departments of mathematics and education in a large, state-supported university. Participants include 300 elementary education students during mathematics content and general pedagogy courses. Results suggest that most prospective teachers changed their conceptions of mathematics and its teaching and learning during this program. Specifically, changes were made in two areas: appreciation of role of content knowledge in designing and implementing instruction, and perception of mathematics as more than rules to be memorized.

This research paper reports first year findings from a multi-year (2001-2004) study that examines changes in prospective elementary teachers' conceptions related to conceptually based mathematics teaching and learning. This study is the result of a *design experiment* (Brown, 1992) advanced between traditionally distinct departments of mathematics and education. Our efforts respond to a current dilemma in teacher education. Students often leave teacher education programs with the same preconceived notions about content, teaching and learning as when they enter (Ball, 1988; Murphy, 1990). One contributing factor is that many teacher education programs, particularly at the elementary level and in mathematics, do not connect across content and method throughout the entire program (Ishler, Edens, & Berry, 1996). Although students traditionally take courses in mathematics, general pedagogy and mathematics education, these courses often do not stress conceptual understanding of content. Many programs do not make conceptual understandings explicit enough to challenge previous conceptions of mathematics, nor do they place these new understandings within the larger context of teaching (e.g., Borko et al., 1993).

Our designed program seeks to assist prospective teachers in developing an orientation that promotes conceptually based mathematics instruction. We are defining "orientation" to include a teacher's knowledge, beliefs, and understandings about mathematics and mathematics teaching which frame his/her thinking and decision-

making as it relates to practice (Magnusson, Palincsar, Marano, Ford & Brown, 1999). To this aim this study investigates the following questions: (1) WHAT changes occur in prospective elementary teachers' orientations toward mathematics and its teaching and learning?, and (2) HOW can an integrated program that promotes conceptually based understanding facilitate change in prospective teachers' orientations?

This paper examines findings related to the first research question.

### **Theoretical Framework**

This study draws on areas of research in mathematics teacher education related to teacher orientation and teacher change. Prospective teachers struggle with how to balance their mathematical anxiety and narrow mathematics orientation with their professed desire to teach in ways that reflect reform expectations (e.g., Benken & Wilson, 1996, 1998; Borko, Davinroy, Bliem, & Cumbo, 2000; Thompson, 1992; Wilson & Goldenberg, 1998). National (e.g., NCTM, 2000) recommendations call for an approach to mathematics teaching that allows students to communicate, problem solve, and engage in cooperative, conceptual mathematical activities. This shift toward more "inquiry based" instruction assumes teachers view mathematics as a tool for thought, rather than a set of rules and procedures to be memorized. However, prospective teachers' orientations are deeply embedded and difficult to change (Ball, 1990; Richardson & Anders, 1994); they are unlikely to make adjustments in their thinking without intervention and deliberate support.

Research on teacher change indicates that programs can facilitate changes in orientation within the context of educational reform (e.g., Richardson & Placier, 2001). To help prospective teachers develop their orientations the connection between content knowledge, beliefs, and pedagogical knowledge must be considered (Stipek, Givvin, Salman, & MacGyvers, 2001). Knowledge of subject matter and general pedagogy help form pedagogical content knowledge (Marks, 1990), and therefore both types of knowledge must be examined.

To develop orientations that promote teaching mathematics for conceptually based understanding, we developed a model that incorporates the relationship among three primary tenets critical to mathematics teacher education: mathematical content knowledge, pedagogical content knowledge (Magnusson, Borko, & Krajcik, 1999; Shulman, 1987) and mathematics teaching practice (Fennema & Franke, 1992) (Fig. 1). This model illustrates the important role mathematical content knowledge plays in forming one's orientation, which then serves as a lens through which pedagogical content knowledge, and later mathematics teaching practices, are developed. Our experiment addresses the connections among these elements early and jointly within the elementary education program experience. Although research has looked at one or two of these components in isolation (e.g., Brown & Borko, 1992; Hashweh, 1987; Wood, Cobb, & Yackel, 1991), few have investigated the interactions among all three (Fennema & Franke, 1992).

# Orientation's Role in the Teaching of Mathematics

### Methodology

This study takes place at a comprehensive institution serving over 14,000 students. With approximately 300 elementary education undergraduates graduating per year, the elementary education program is considered a substantial program both within the university and across the country.

Within the required elementary teacher education courses, there are three primary courses within which we are focusing our efforts related to mathematics education reform: mathematics content course, professional development course in instructional design, and mathematics methods course.

### Design Experiment

The goal of our design experiment is to create an elementary mathematics teacher education program that addresses and develops students' orientations as a systemic objective. To allow time to foster new orientations we aligned previously disconnected courses in mathematical content and pedagogy throughout the required mathematics strand. Course goals reflect our common orientation toward teaching and teacher education, including active knowledge construction, opportunities for on-going reflection, focus on enduring mathematical understandings, and modeling teaching practices that support these tenants. These goals are critical in achieving teacher change (Richardson & Placier, 2001).

### Data Sources

This paper examines data collected from elementary education students ( $n=300$ ) during the first year (2001-2002) of a three-year research project. Project data sources include: (1) orientation surveys, (2) course artifacts, (3) content knowledge exams, and (4) semi-structured interviews. This paper explores results from surveys and course artifacts.

Orientation surveys were distributed at the beginning and end of two courses: mathematics content and general pedagogy. The content survey garners information about participants' overarching conceptions related to mathematics and its teaching. The pedagogy survey asks participants to elaborate their understanding of teaching and learning. Most survey questions (e.g., "Mathematics involves mostly facts and procedures to be learned," "It is important for teachers to have a thorough understanding of the subject he/she is teaching") use a Likert-type scale (1-5). End of course surveys also ask participants to reflect on their experiences related to specific course activities, and how these courses may have influenced mathematics orientation. Administering surveys at the beginning and end of these courses allows for interpretation of changes in individual participants' orientations and comparisons across individuals throughout the program.

Artifacts (course assignments) were collected from *experimental* sections (taught by principal researchers). Assignments were designed to allow students to make

explicit connections between being a learner of mathematics and a prospective teacher of those mathematical understandings. Assignments deliberately create cognitive conflicts (Pajares, 1993), which challenge students' conceptions, facilitate reflection, and provide opportunity for expanded thinking.

### Analysis: Three Phases

- (1) Data was analyzed using *direct interpretation* (Stake, 1995) to garner emergent themes and patterns within individuals to understand the substantive changes in prospective teachers' thinking. Specifically, coding illustrated what changes occurred in prospective teachers' orientations toward mathematics, as well as mathematics teaching and learning.
- (2) Data was *aggregated* (Stake, 1995) across individuals to understand growth in orientations across all individuals within each course.
- (3) What was learned in the second phase was used to make comparisons between experimental and non-experimental sections.

In essence, case studies will be done at three levels: individual students, course section, and course design.

Validity issues are addressed by the following: (1) data is triangulated across multiple sources, (2) coding is done independently by two researchers, allowing for cross-validation of results, and (3) external validity of coding is explicit in the multi-stage nature of the research project.

### Results

Preliminary results suggest that most (approximately 85%) of the prospective elementary teachers in experimental sections changed their orientations towards mathematics, as well as its teaching and learning. Specifically, changes were made in two areas: (1) appreciation of role of content knowledge in designing and implementing instruction, and (2) perception of mathematics as problem solving. In the first area, participants recognized that their own understanding of content is critical to the design and implementation of instruction. As one prospective teacher stated, "We all have different ideas about different subjects, and everything we teach will be influenced by our own understandings and beliefs about that subject." By the end of pedagogy course activities, participants also saw content knowledge as being an important attribute of a "good" teacher. This reflects a dramatic change from themes during the beginning of the course; most participants only referred to affective attributes, e.g., "caring," "kind," and "loves children." In addition to recognizing the important role of their own understanding of content in instruction, these prospective teachers also referred to their students' understanding of content as being a primary goal of instruction.

In the second area, participants changed their views of mathematics as a discipline. For example, many participants who understood mathematics as static and

comprised of rules to be memorized, later described it as complex, changing, and open-ended. By the end of the mathematics content course, almost all participants referred to mathematics as involving problem solving, using multiple approaches, and as necessary to solve problems in real-life situations. As one participant stated, "I now [after taking this course] realize there are different ways to approach problems." Changes in orientation were less evident in non-experimental sections.

Comments made by prospective teachers in end of course surveys and on course assignments indicate that the collaboratively designed activities helped to scaffold this change. For example, many participants explained that writing about their understandings forced them to reflect upon and connect those understandings. Even during the mathematics content course (often taken prior to the instruction and design course) participants commented on the need to understand content in flexible ways to best help their students understand these concepts. As one participant stated, "The more methods and strategies I learn in problem solving, the easier it will be to get concepts across to students." These findings suggest that when programs are purposely designed to understand and address students' thinking about content and pedagogy early and connectedly in a program, changes can be made in mathematical orientations that will ideally lead to conceptually based teaching.

What we find compelling related to these results is that while these prospective teachers of mathematics grew in their understanding of and orientation toward mathematics and recognize the important role these understandings play in implementation of instruction, they often *design* mathematics instruction to reflect a more directive style. Reasons include difficulty of mathematics as a subject and wavering confidence in their developing mathematical orientations. Our continued research project will now follow these prospective teachers into their elementary mathematics methods course and student teaching experience. We anticipate that students will strengthen these tenuous connections as they experience teaching mathematics in more reform-oriented ways.

This study contributes to what is understood about prospective teachers' thinking concerning mathematics and its teaching and learning. Within this design experiment our shared vision of conceptually based mathematics education was able to be realized by collaboratively incorporating efforts early and connectedly in the teacher education process, thus stimulating interdisciplinary research in mathematics and elementary teacher education.

# GROWTH IN MATHEMATICAL UNDERSTANDING WHILE LEARNING HOW TO TEACH: A THEORETICAL PERSPECTIVE

Laurie O. Cavey  
North Carolina State University  
locavey@unity.ncsu.edu

This theoretical paper outlines a conceptual framework for examining growth in prospective teachers' mathematical understanding as they engage in thinking about and planning for the mathematical learning of others. The framework is based on the Pirie-Kieren (1994) Dynamical Theory for the Growth of Mathematical Understanding and extends into the pedagogical realm by assuming that growth in mathematically specific understanding for teaching is a dynamical, leveled but not linear, transcendently recursive process of reorganizing one's knowledge. Data from a preliminary case study is shared to illustrate how the framework can be used to provide a lens for examining growth in mathematical understanding within the context of learning to teach high school mathematics.

Determining ways to challenge and extend prospective teachers' ideas about *school mathematics* (the mathematics they will teach) is recognized as one of the most important matters to be considered by mathematics educators today (Conference Board of Mathematical Sciences (CBMS), 2001; Sowder et al., 1998). To break the perpetual cycle of inadequate knowledge of school mathematics, teacher preparation leaders were advised to modify their programs of study to provide better preparation for future teachers in both *university mathematics* (typical college mathematics courses) and school mathematics. This situation leaves teacher preparation program leaders faced with deciding exactly how mathematics preparation can be accomplished both efficiently and meaningfully without neglecting the much-needed time for pedagogical development.

Research results (Berenson & Cavey, 2000; Bowers & Doerr, 2001; Cavey, Berenson, Clark, & Staley, 2001; Clark, 2001; Ma, 1999) suggest that engaging prospective teachers in *teaching tasks* (thinking about and planning for the mathematical learning of others) may be an effective way of addressing both content and pedagogical developmental needs. Bowers and Doerr (2001) engaged prospective and practicing teachers in computer-based activities as learners of the mathematics of change (rate of change) and then as teachers of rate of change and observed both mathematical and pedagogical insights made by the prospective and practicing teachers as they were engaged in both types of activities (as learners & as teachers). Berenson and Cavey (2000), Cavey, Berenson, Clark, and Staley (2001), and Clark (2001) conducted preliminary studies to investigate the plausibility of using an experimental curriculum, "lesson plan study" (LPS), to promote growth in prospective teachers' understanding of school mathematics and teaching strategies. As LPS participants, prospective sec-

ondary mathematics teachers engaged in multiple conversations with others (researchers and peers) about teaching a specific secondary mathematics topic. Such conversations occurred over five weeks on the same lesson topic and seemed to promote growth in prospective teachers' understanding of school mathematics (Berenson & Cavey, 2000) and teaching strategies (Cavey et al., 2001; Clark, 2001).

The use of these teaching task methodologies leads to theoretical questions about prospective teachers' growth in mathematical understanding. As such, a conceptual framework was developed to provide a lens for examining prospective teachers' growth in mathematical understanding as they participated in LPS. Here, I briefly describe each component of the conceptual framework, the first activity of LPS, and provide an example to illustrate how the framework can be used.

### **The Pirie-Kieren Model: Growth in Mathematical Understanding**

The Pirie-Kieren (1994) Dynamical Theory for the Growth of Mathematical Understanding depicts understanding as a dynamical, leveled but not linear, transcendently recursive process of reorganizing one's knowledge. The model is a theory for the growth of understanding of a specific mathematical topic by a specific 'person' over time and is comprised of layers of sophistication in thinking that describe the mental activities necessary for growth in mathematical understanding of a particular topic. It is assumed that a learner comes to a particular learning situation with primitive knowledge [all knowledge *not* related to the particular topic] as well as some knowledge of the particular topic, identified by some outer layer of thinking. The seven outer layers of thinking are: Image Making, Image Having, Property Noticing, Formalising, Observing, Structuring, and Inventising.

Pirie and Kieren (1994) asserted that each of the seven outer layers "is composed of a complementarity of *acting* and *expressing*" where "acting encompasses all previous understanding, providing continuity with inner levels, and expressing gives distinct substance to that particular level" (p. 175). Both acting and expressing involve mental as well as physical actions. Through acting, the learner may reflect on how their previous understanding applies to a new learning situation. When expressing, however, the learner makes it clear to oneself or others what knowledge was gained. The terms used for acting/expressing complementarities within the image making, image having and property noticing layers are doing/reviewing, seeing/saying, and predicting/recording.

Critical to the theory is the idea of recursion—that learners revisit layers of thinking in the process of extending their mathematical understanding. Layers are revisited with more sophisticated thinking along one thread of a particular topic in an attempt to broaden and deepen knowledge of that topic. Folding back is the term used to describe the mental activity of accessing one's more primitive knowledge to construct mathematical understanding at an outer layer of thinking. This notion exemplifies the idea that an individual's mental activities do not move in one direction. Rather, an indi-

vidual functioning at an outer level of understanding will repeatedly return to an inner level to extend their mathematical understanding (Martin, 1999). For example, in formalising his or her understanding of fractals, a mathematician may fold back to his or her knowledge of complex numbers to understand why fractals portray self-similarity. In comparison, an elementary student may fold back to his or her knowledge of whole numbers to develop a rule for finding a common denominator while formalising his or her understanding of the fraction concept.

A deeper look at folding back (Martin, 1999) reveals the complex nature of this process. In particular, not all acts of folding back are necessarily effective in extending mathematical understanding. Research results indicated that the effectiveness of folding back depends on both the structure of the environment and the individual learner and that folding back tends to be more effective when the learner is prompted to fold back to collect specific information (Martin, 1999). This type of folding back, collecting, "occurs when students know what is needed to solve a problem, and yet their understanding is not sufficient for the automatic recall of useable knowledge" (Pirie & Martin, 2000, p. 127).

### **Extending the Pirie-Kieren Model into the Pedagogical Realm**

The framework is extended into the pedagogical realm by assuming that *teaching mathematics understanding* (understanding enacted when making decisions about the mathematical learning of others) draws upon three mathematically specific understandings: mathematics, mathematics teaching strategies, and mathematics learning. While it is obvious that teaching mathematics understanding draws upon other primitive knowledge types, such as understanding human behavior, the research for which this framework was developed is primarily focused on examining the development of the aforementioned mathematically specific knowledge domains.

It is assumed that growth in such understandings can be modeled as Pirie and Kieren (1994) modeled growth in mathematical understanding and that prospective teachers begin their teacher preparation programs, specifically their first methods course, with some level of understanding of mathematics, mathematics teaching strategies, and mathematics learning. Indeed, beginning prospective teachers typically have an outer layer understanding of mathematics and mathematical learning developed through coursework and other life experiences and images of teaching strategies developed through observation. Such outer layer understandings can constrain additional growth in prospective teachers' understanding of school mathematics (Benson & Cavey, 2000) when prospective teachers do not see the need to revisit certain mathematical ideas. See Figure 1 for an illustration of how the Pirie-Kieren model is extended into the pedagogical realm.

Figure 1. Content-Specific Primitive Knowledge Domains Accessed While Learning To Teach Mathematics.

### Right Triangle Trigonometry LPS: The Framework In Action

Data from a preliminary case study is used to illustrate how the framework provides a lens for examining growth in mathematical understanding while one prospective teacher participated in a LPS. This LPS was conducted at the beginning of an introductory methods course for prospective secondary mathematics teachers at a large public university and focused the participants on teaching right triangle trigonometry. Data for one participant, Molly (pseudonym), are shared from the initial planning activity [preliminary interview, lesson planning, and post-planning interview], in the form of videotaped interviews and written artifacts. Table 1 contains a summary of the tasks included in the first activity of LPS focused on teaching right triangle trigonometry.

**Table 1.** Initial Planning Activity of the Right Triangle Trigonometry LPS

| Task                  | Description  | Duration |
|-----------------------|--|----------|
| Preliminary Interview | Videotaped conversation between a researcher and a prospective teacher about what the prospective teacher remembered learning about right triangle trigonometry and preparation for lesson planning.                       | 20 min   |
| Creating Plan 1       | Immediately after the preliminary interview, the prospective teacher was left alone with resources (texts, manipulatives, etc.) to plan a lesson to introduce right triangle trigonometry to a high school geometry class. | 45 min   |

### Initial Growth in Understanding Right Triangle Trigonometry

#### Image Saying

Even though Molly had difficulty remembering what and how she learned right triangle trigonometry, she shared two images of her understanding during her first meeting with the interviewer (the preliminary interview). One image was based on the memorization of an acronym whereas the other image was centered on using right triangle trigonometry to solve for an unknown angle measure. When Molly was asked about what she remembered learning about right triangle trigonometry, the following dialogue occurred.

Molly: I remember cosine, sine, and tangent.

I: Okay. Go ahead and write that down while you're explaining this. I want to know everything that you remember. [Molly wrote 'cos', 'sin', and 'tan' on her paper, with 'tan' directly below 'sin' and 'sin' directly below 'cos'.]

Molly: I don't remember all that much.

I: That's fine.

Molly: One thing that stands out is they told me something like socatoa. I'm trying to remember which one goes with which one. [Molly first wrote 'SOCA', then erased 'CA' and wrote 'HCAHTOA' so that 'SOHCAHTOA' was written across the top of her paper.] If I have this right, then this would mean that if you use sine, then you have opposite over hypotenuse, and if you use cosine, you have adjacent over hypotenuse, and if you had tangent, you had opposite over adjacent.

The subsequent conversation indicated that Molly recalled using right triangle trigonometry to determine an unknown angle measure. When asked about how right triangle trigonometry is used, Molly stated, "If you have a right triangle, the sides of it to try to figure out the angles, is all I remember." She seemed to be recalling a way of using right triangle trigonometry to determine an angle measurement by using the measurements of two sides of a right triangle.

Molly was clearly not confident in her ability to recall these or other ideas related to right triangle trigonometry. When asked about what she remembered about what her teacher showed her, Molly remarked, "All I remember is that sohcahtoa thing that stands out to me. I just remember cosine and sine." Molly recognized her limited memory and planned to 'fix' the problem through review. After Molly received instructions for the lesson-planning component, she asked, "Can I use these books to refresh?" Such an inquiry indicates that Molly planned to fold back and collect information about right triangle trigonometry for the purpose of planning her lesson.

### **Folding Back to Collect**

As Molly created her first plan, she folded back to collect mathematically precise information concerning many ideas related to right triangle trigonometry. As indicated by her lesson plan notes, Molly folded back to collect 1) the definition of a right triangle, 2) the Pythagorean theorem, 3) definitions for sine and cosine, 4) the relationships between side lengths for 30-60-90 & 45-45-90 triangles, and 5) a definition for similar triangles. All items collected, except for the definition of similar triangles, were incorporated into her first plan.

Molly's collecting indicates that she valued mathematically precise definitions in her own learning and provides insight into her growth in understanding of right triangle trigonometry. Just the fact that four items were collected, in addition to the definitions of sine and cosine, indicates that Molly's right triangle trigonometry understanding thickened to include connections to the Pythagorean theorem, right triangles, relationships for special right triangles, and similarity. Collecting more precise definitions for sine and cosine indicates additional thickening in her understanding. By considering how these items were incorporated into her first plan, I gained additional insight on how her understanding of right triangle trigonometry changed.

Molly's first plan seemed to be geared towards solving for missing parts of right triangles. By starting the lesson with the definition of a right triangle, she set the stage for the context of the lesson. The Pythagorean theorem was viewed by Molly as a way "to calculate the unknown measure of a side of a right triangle given the measures of the other two sides." For Molly, this led directly to the definitions of sine and cosine since she thought of right triangle trigonometry as a way to find an angle measure based on the measures of two sides. In other words, she thought of both the Pythagorean theorem and right triangle trigonometry as means for 'solving for missing parts of right triangles'. Molly thought of the Pythagorean theorem as a means for using two

side lengths to determine the third side length, whereas right triangle trigonometry was thought of as a means for using two side lengths to determine an angle measure. The relationships among the sides of triangles with angle measures 30-60-90 and 45-45-90 triangles seem to have been included to simplify the process when working with these types of triangles. Hence, Molly's understanding of right triangle trigonometry was thickened by connecting to mathematically precise information in relation to 'solving for missing parts of right triangles'.

Folding back to collect mathematically precise definitions for sine and cosine thickened Molly's understanding of right triangle trigonometry further. In her written notes, sine and cosine were referred to as ratios of the measures of sides. She wrote, "Sine is the ratio of the measure of the leg opposite the acute angle to the measure of the hypotenuse." She also referred to sine and cosine as ratios during the post-planning interview, indicating that she was image saying and had indeed remade her image of sine and cosine.

In essence, by the time she finished planning her first lesson, Molly collected mathematically precise definitions and relationships for topics she understood to be immediately connected to 'solving right triangles'. Collecting this information and incorporating the ideas into her lesson thickened Molly's knowledge of right triangle trigonometry.

## **Growth in Understanding Similarity**

### **Image Saying**

In her notes for plan 1, Molly wrote, "Similar triangles have 3 angles of 1 triangle congruent to 3 angles of another triangle and the measures of their corresponding sides are proportional." However, she had not incorporated the idea into her first plan and she struggled to explain the concept when prompted to do so during her second meeting with the interviewer. When Molly was asked how she might help a student understand similarity, she suggested a plan that started with giving the student the definition and then showing some examples. When asked to describe similarity she stated, "It's when two triangles have angles that are similar to one another." Molly was not confident in this response and quickly added, "I would have to look that up. I'm not sure to be honest with you," which indicates that Molly was interested in collecting more information on similarity.

### **Folding Back to Collect**

The interviewer immediately prompted Molly to consider two triangles drawn on a separate piece of paper and asked how she would know if they were similar. Molly drew two right triangles and the following dialogue occurred.

I: Do they have to be the same size to be similar?

Molly: [Pause] No.

I: If they don't have to be the same size, what makes them similar?

Molly: If they are both right triangles, with maybe their angle measures the same, 45-45 or 30-60. As long as all three angles are the same, then they're similar, but they can have different lengths.

This dialogue seemed to help Molly rethink the relationship between corresponding angles of similar triangles, thereby remaking her image of similar triangles. It appears that she folded back to mentally collect part of the definition for similar triangles she had written in her lesson plan notes.

### **Summary of Molly's Growth in Mathematical Understanding**

During the first meeting with the interviewer, Molly exhibited a limited understanding of right triangle trigonometry. In fact, Molly started the LPS with two images of right triangle trigonometry, the SOHCAHTOA acronym and the image of using right triangle trigonometry to determine angle measures. However, opportunities to share her mathematical images seemed to help Molly become aware of gaps in her own mathematical understanding and subsequently plan to collect mathematical information. In addition, as Molly made images for teaching right triangle trigonometry, she folded back to her mathematics understanding to collect, revise, and construct images of mathematics related to right triangle trigonometry. In addition, during subsequent LPS components, Molly repeatedly folded back to revise her understandings of right triangle trigonometry and related primitive knowledge domains. In particular, Molly revisited the ideas of ratio, similarity and the Pythagorean theorem in relation to right triangle trigonometry. An illustration of the primitive knowledge domains that Molly accessed while extending her mathematical understanding during LPS is provided in Figure 2.

### **Discussion and Implications**

By placing the learning of school mathematics within the context of teaching tasks, prospective teachers rely on their teaching mathematics understanding and are thereby forced to fold back to their understandings of mathematics, teaching strategies, and mathematical learning to make decisions about the mathematical learning of others. However, there is much to be learned about the effectiveness of using teaching tasks in adding depth, breadth, and thoroughness (Ma, 1999) to prospective teachers' mathematically specific knowledge for teaching. Particularly, more research is needed to ascertain the effectiveness of using LPS to extend prospective teachers' mathematics teaching understanding.

The framework presented here provides a lens for examining growth in mathematically specific components of teacher knowledge (mathematics, mathematics teaching strategies, and mathematics learning). Initially developed to examine growth in prospective teachers' mathematical understanding as they participated in LPS, the framework can also be used to examine growth in prospective teachers' understanding

Figure 2. Primitive knowledge domains in mathematics understanding that Molly accessed during LPS.

of teaching strategies and/or mathematics learning. In addition, the framework can be used to examine growth in teaching mathematics understanding for any learner engaged in making decisions about the mathematical learning of others. Applying the framework to other teacher-learning situations is expected to contribute to understanding how teachers learn to teach mathematics. At a very minimum, future applications of this framework must consider the thoughts and actions of prospective teachers when interacting with k-12 students.

#### Note

<sup>1</sup>'Person' can refer to an individual learner or any size group of learners. Essentially, it can be thought of as a 'learner unit', comprised of any number of individuals that are jointly learning.

# **UNDERSTANDING CHANGE: EPISTEMOLOGIES OF THREE FUTURE TEACHERS OF ELEMENTARY SCHOOL MATHEMATICS**

Jennifer Chauvot  
San Diego State University  
jchauvot@math.sdsu.edu

The purpose of this study was to understand 3 prospective teachers' epistemologies of knowledge in general and then specifically in the knowledge domains of mathematical knowledge (MK), mathematics learning knowledge (MLK), and mathematics teaching knowledge (MTK) as they participated in an early mathematical field experience at an elementary school. The analysis revealed that the participants' epistemological views for knowledge in general were helpful in understanding changes (or no changes) in epistemological views in MK, MLK, and MTK. Although the 3 participants shared many common experiences, how they perceived the experiences was very different.

Prospective teachers frequently encounter ideas about teaching mathematics that differ from their own mathematics learning experiences. Models that describe epistemologies (Baxter Magolda, 1992; Belenky, Clinchy, Goldberger, & Tarule, 1986; Kitchener, 1983; Perry, 1970/1999) are helpful in understanding how individuals perceive these ideas. Such models highlight that individuals who adhere to different epistemological stances interpret and respond to the same learning environment in different ways. Related work in mathematics education (Cooney, Shealy, & Arvold, 1998; Copes, 1982) supports this view. Understanding prospective teachers' epistemologies can contribute to theory about learning to teach mathematics, which will aid in the design and implementation of teacher education programs.

The purpose of this study was to understand three prospective teachers' epistemologies, or views of the nature and justification of knowledge, in general and then specifically in the knowledge domains of mathematical knowledge (MK), mathematics learning knowledge (MLK), and mathematics teaching knowledge (MTK) throughout their teacher education program. In this paper I report the results from the first semester of the study.

## **Theoretical Framework**

Models that describe epistemologies indicate that individuals who adhere to different epistemologies have different orientations regarding who counts as a source or what counts as evidence for knowledge and to what extent that knowledge is certain. Essentially, the extent of certainty of knowledge ranges from knowledge perceived as certain and free of context and human values to knowledge as relative and based in context and personal interpretations. Sources of knowledge are characterized as predominantly external (e.g., perceived authorities), predominantly internal (e.g.,

personal experiences, intuition), or a blend of both. What counts as evidence for knowledge is directly related to source, in that an individual assumes that information is correct on the basis of what an authority says, personal experiences (it worked for me), intuition (it feels right), reasoned judgment (this is how we agree to resolve differences), or some combination thereof.

Another characteristic for describing one's epistemology is an individual's willingness to entertain multiple perspectives. First, if sources of and evidence for knowledge tend to be based on perceived authorities, for example, then an individual tends to assume that a question has only one right answer. A prospective teacher who adheres to such a view may be inclined to look toward instructors of mathematics education courses for *the* way to do mathematics or *the* way to teach mathematics (e.g., Mewborn's (1999) participants in Stage 1). He or she may prefer learning environments in which discussions of multiple perspectives on a topic are not promoted.

Second, a learner may tend to focus on internal sources of knowledge. The term *internal* is intended to imply a focus on self and intuition or a focus on others as intuitive individuals. Certain answers exist *for oneself* on the basis of personal experiences and intuition. Certain answers exist *for others* on the basis of their personal experiences and intuition. Multiple perspectives are considered legitimate, and knowledge is considered uncertain because of one's inability to fully understand the experiences of others. A prospective teacher from this perspective may appreciate whole and small-group class discussions in mathematics education courses but might be unwilling to evaluate others' views because he or she believes that everyone has the right to his or her own opinion or that everyone has his or her own interpretation of an experience (e.g., Brenda in Chauvot, 2001, or see Wilson & Goldenberg's (1998) discussion of *extreme relativism*).

Third, a learner may expect environments that promote multiple, legitimate perspectives in some contexts but not in others. A prospective teacher may expect a multiplicitic environment in a methods course but not in a mathematics course. Evidence for knowledge varies according to the context and the individual's tendencies toward accepting external or internal knowledge sources.

### Methodology

The study began when the prospective teachers participated in an early mathematical field experience designed to challenge traditional beliefs about mathematics and its teaching and learning. Purposeful sampling strategies (Patton, 1990) were used to select Jenna, Debbie, and Gail. Their responses on an open-ended belief survey showed that they held different epistemological stances. For example, the variation in their rationales to "When you are a teacher, will you ever ask your students to solve a new kind of problem without first showing them how to solve it?" indicated that sources of mathematical knowledge varied across participants. Gail said that she will not pose such problems, and she relayed a desire for students to imitate the teacher,

whereas Debbie will, and she argued that the children could be successful without help from the teacher. Jenna will, as well; her rationale indicated that she intended to “fix” children’s thinking to move toward a predetermined mathematical goal.

A university instructor directed the field experience for 2 1/4 hours per week at an elementary school. Three main components of the field experience were (a) video clips illustrating different ways children approach mathematical tasks, (b) carefully designed interviews with children, and (c) small and whole-group discussions and writing assignments about the videos and the interviews (see Philipp, Thanheiser, & Clement, 2002.) All three participants were concurrently taking the first of four mathematics courses for elementary teachers.

Data sources for this study were Baxter Magolda’s (1992) Measure of Epistemological Reflection (MER), a semistructured interview, and a class-log writing assignment. All interviews were audiotaped and transcribed. Data from the field experience and the mathematics course included the pre- and post-belief-survey, a mathematics autobiography, and writing assignments about the videos and the interviews.

Data analysis of the MER followed Baxter Magolda’s (2000) recommendations for interpreting participants’ responses. The additional data were used to confirm or disconfirm this analysis. The data were then reviewed again to ascertain more specifically who or what the participants viewed as sources of and evidence for MK, MLK, and MTK, and to what extent they viewed that knowledge as certain.

## Results

### Sources, Evidence, Certainty of Knowledge

The analysis pertaining to knowledge in general revealed that both Jenna and Gail had multiplistic tendencies. Both preferred classes that focused on ideas or concepts rather than on factual information, because the former required more “thinking” (as opposed to memorization) and were often structured in such a way that exposed them to their peers’ thinking and ideas. In terms of evidence for knowledge, both Jenna and Gail showed reliance on the instructor for sorting through ideas. Gail, however, also seemed to expect some form of rationale from her peers. She liked that small-group activity “forces everyone to have an opinion about a particular topic and be able to defend it.” Gail frequently spoke of a “personal interpretation” that seemed to influence what counted as evidence for knowledge. She preferred courses about ideas because, she said, “I am able to make an interpretation of the discussions based on my own personal viewpoint. There [are] many possibilities for a correct answer, based in part on your own understanding of the subject matter.”

Gail preferred to be what she called an *active listener* in her courses:

I like to listen to everyone’s point of view. I do have a point of view, but I don’t like sharing it. I compare my point of view to their point of view and just make a conclusion out of it.

Gail's position held across all her courses whereas Jenna described her role in the classroom as dependent upon the content. For example, Jenna argued that her role in her history and geology courses was "pretty much sitting and listening"; there was no room for discussion.

Debbie preferred courses that focused on factual information because "there's no gray area." She believed that her interactions with peers or instructors should remain at a minimum. She saw no need to attend a class if the instructor intended to merely follow the book. She preferred "sitting back and listening" and rarely asked questions in her courses because frequently her peers asked questions for her. Debbie did not value her peers as knowledge sources; they served as tools for obtaining knowledge from her instructors. She trusted what her instructors had to say about the content and her own ability to teach herself (from the textbook), if needed. Like Gail, she felt that her role in the classroom was the same across all her courses.

### **Sources, Evidence, Certainty of MK**

The initial data indicated that for all three participants, sources of and evidence for MK for themselves and for children resided with the instructor, the textbook, or both. For example, Gail described her past mathematics learning experiences as "the more the teacher was able to explain a topic to me with as little confusion as possible, then I would be fine." All three participants acknowledged that mathematics was more than a set of rules and procedures. They reported that learning mathematics should be more than memorization and that they wanted children to understand "the whys" of algorithms. The participants gave no indication that they viewed MK as a knowledge domain that involved context or personal interpretation.

The mid- and end-of-semester data provided opportunities to ascertain changes (or no changes) in the participants' epistemological views in MK. All three claimed that the field experience allowed them to see that one can approach mathematical problems in multiple ways and that this notion was different from their own mathematics learning experiences. For example, Gail commented favorably about a video clip in which the teacher asked students to share their strategies with the entire class. She noted,

When I was their age, it was the teacher who was the sole instructor of the class, leaving little room for insight amongst my classmates.... [I liked how] the other students along with the teacher can compare and contrast different methods and see which ones are wrong or right.

Her comments indicated that Gail had begun to value children as their own sources of MK and that the children and the teacher should decide what counted as MK. Gail admitted that mathematics was not as clear-cut as she had thought and that mathematics involved abstract thinking as well: "It's abstract in the way you arrived at the answer and how you think of the problem and how other people [think of the prob-

lem].” In fact, there were several indications that both Jenna and Gail wanted children to be their own sources of MK; personal interpretation was involved, and “what made sense” served as evidence for that knowledge.

As another example, Jenna’s post-response regarding whether or not she would ask students to solve a new kind of problem without first showing them how to solve it was “Yes. So they can come up with their own algorithms that make sense and work for them.” Jenna made similar comments in papers she wrote about her interviews and in her descriptions of her own learning of MK throughout the semester: “It’s a lot of how you see things, and how you interpret things, instead of just, ‘Do it this way. Memorize it.’” Jenna and Gail seemed to now have a more personal approach in their thinking about MK.

Compared to Jenna and Gail, Debbie gave fewer indications of epistemological change in the domain of MK. One theme that was consistent with Debbie was a focus on the importance of conceptual understanding. However, Debbie seemed to continue to see herself as the source of MK for her future students. She felt that familiarizing herself with different ways children approached mathematical problems would help *her* “explain how to do things.” She did not value having the children share the multiple strategies. “I think that it is important to only show the kids a single way to do it until they have an advanced understanding of the type of problem they are learning.”

### Sources, Evidence, Certainty of MLK and MTK

Essentially, MLK and MTK *became* knowledge domains for Jenna and Gail. They had not previously thought about either how children think about mathematics or how to teach mathematics. Jenna commented, “I have never thought of teaching math as very important, or never a big deal in the classroom. [I now] realize the importance of how you teach math.”

For both Jenna and Gail, viewing the video clips, working with children, working with their peers, and receiving guidance from the university instructor all served as sources of MLK and MTK. What counted as evidence for this knowledge were mostly their (now) deeper understanding of mathematics (“I finally understand this algorithm.”) and their interviews with the children (“She did exactly what we talked about in class!”).

Debbie described the field experience as interesting and informing. The video clips of whole-class lessons and of teachers reflecting on their practice were the most valuable to her. She appreciated the “hands on” environment and opportunities to see how kids think about mathematics. But she felt that she had not engaged in teaching: “I’m not teaching anything. I’m just picking their brain.” She described some of the coursework as “busy work” and “extremely repetitive.” She went on to say,

We just interview them. There’s no social aspect of it. It’s pretty much get the job done and, “How did you get that answer?” and then they’ll tell you. You take notes, and then you do write-ups ... [about] what we learned and

what the kid learned. Kind of b.s. [sic] your way through it, and in 2 pages, you're done.

Debbie did not value the field experience in the same way as Jenna and Gail did. She fulfilled the course requirements, but not in a meaningful way.

### Final Comments

Jenna and Gail's multiplistic tendencies coupled with the field experience provided opportunity for acknowledging children's mathematical thinking and considering implications for mathematics and its teaching. Continued data collection will indicate whether and why these changes are sustained. Perhaps a better forum for Debbie would be a context that is more aligned with her (single) notion of what teaching is about and how one learns to teach mathematics. She seemed to discount the field experience because of its structure. She may be one who needs mathematics teaching successes and more importantly failures within whole-class instruction that might prompt her to re-examine her view that the teacher is the sole source of MK.

# **PLACING CHILDREN BETWEEN PROSPECTIVE ELEMENTARY SCHOOL TEACHERS AND MATHEMATICS: THE MATHEMATICAL EARLY FIELD EXPERIENCE**

Lisa Clement                      Randolph A. Philipp                      Eva Thanheiser  
San Diego State University   San Diego State University   San Diego State University  
lclement@mail.sdsu.edu      rphilipp@mail.sdsu.edu      evat@sunstroke.sdsu.edu

To address the problem that prospective elementary school teachers (PSTs) go through even well-designed mathematics courses in a perfunctory manner, we propose a new model, the Children's Mathematical Thinking Experience (CMTE). The CMTE was designed to enhance PSTs' beliefs about mathematics and children's mathematical thinking, by having PSTs work in principled ways with individual children early in their teacher-training experiences. The PSTs come to attend to children's mathematical thinking and then to the mathematics, because they care about the children with whom they work. Our analysis indicates that the CMTE enhanced PSTs' beliefs, and did so to a greater degree than more typical early field experiences.<sup>1</sup>

One cannot teach what one does not know, and so a prospective teacher must understand mathematics to be in a position to teach it. However, we find problematic the idea's translation into practice if prospective elementary school teachers first learn mathematics content and only later consider issues of teaching and learning. First, we know that developing deep understanding of the mathematics of elementary school is far more difficult than was once thought (Ma, 1999; Sowder, Philipp, Armstrong, & Schappelle, 1998). Second, our experience has been that even when prospective elementary school teachers (PSTs) attend a thoughtfully planned course designed to engage them in rich mathematical thinking, too many of them go through the course in a perfunctory manner. Many PSTs' conceptions about what mathematics is-- a fixed set of rules and procedures--along with their perceptions of how children and adults learn mathematics--by being shown how to solve problems in a prescribed step-by-step fashion--interfere with the more conceptual, meaning-making goals of mathematics courses designed for PSTs. We thus believe that there is a better place to begin working with prospective elementary school teachers. As a major part of a large-scale study involving five treatments and 164 PSTs, we have studied a new model for integrating mathematical content and pedagogy, the Children's Mathematical Thinking Experience--Live (CMTE-L<sup>2</sup>). PSTs, while taking their first mathematics course for elementary school teachers, engage with children's mathematical thinking by interviewing and tutoring elementary school-age children.

The purposes of this paper are thus to provide (a) a rationale for providing PSTs opportunities to work with children early in their programs, (b) a brief description of the CMTE-L, and (c) evidence that the CMTE-L changed PSTs' conceptions about

mathematics and how children learn it to a greater degree than more typical early field experiences.

### **Why Focus on Children's Mathematical Thinking?**

The widely accepted notion that children learn by building upon their existing knowledge might be taken as an axiom of learning. David Ausubel stated, "If I had to reduce all of educational psychology to just one principle, I would say this: The most important single factor influencing learning is what the learner already knows" (quoted in Hiebert & Carpenter, 1992, p. 80). We adapt Ausubel's comment to include not only what the learner knows but also that about which the learner cares. We believe that we can facilitate the process by which PSTs come to learn mathematics by beginning with what PSTs care most about—children. We place children (rather than children's thinking, for example) at the center of caring because we believe that for most PSTs, the initial caring is a phenomenological act of concern for the whole child versus for a particular characteristic of the child. We hypothesize that when PSTs engage children in mathematical problem solving, the PSTs come to care about children's mathematical thinking. PSTs begin to see how children think about mathematics and come to recognize that children solve problems in varied and sometimes mathematically powerful ways. It is then that PSTs' caring will extend to mathematics, because they realize that to be prepared to understand the depth and variety in children's mathematical thinking, they must themselves grapple with the mathematics.

### **How Do We Focus on Children's Mathematical Thinking?**

Our approach to integrating mathematics content and pedagogy is through the CMTE-L we created to provide PSTs opportunities to interview and tutor children in mathematics and to reflect upon the process. The CMTE-L is a course held weekly for 2 1/4 hours in a classroom on-site at a local elementary school. The course addresses children's mathematical thinking and mathematics, and although it is neither a mathematics course nor a mathematics methodology course, it combines aspects of both. The CMTE-L is different from a mathematics course because the mathematics studied is not an end in itself but instead arises from the PSTs' work with children. Furthermore, the MEF is different from a mathematics methodology course because we do not attempt to help students learn to teach a group of students. For example, we do not discuss lesson planning or classroom management. We do not consider how children might learn from one another, because PSTs work with only one child at a time, a model selected for two reasons. First, by working with only one child, PSTs can focus solely on one child's mathematical thinking. Second, when experiencing difficulties understanding the child's thinking or considering ways to support the child, the PSTs must grapple with the child's reasoning, because neither the child nor the PST can turn to other children for help (cf. Thompson & Thompson, 1994). In the CMTE-L, PSTs work directly with children in about half of the 13 sessions; other times they

analyze previous sessions with children, plan subsequent sessions, discuss video clips of children solving mathematics problems, or consider more general issues related to children's thinking or mathematics. The PSTs in the CMTE-L are concurrently enrolled in the first of four mathematics content courses required of PSTs.

In the first part of the course, the PSTs examine the mathematical thinking exhibited in young children's solution strategies for various types of mathematics problems (Carpenter, Fennema, Franke, Levi, & Empson, 1999). The PSTs learn to conduct an assessment interview and then, working in pairs, conduct an interview with a primary-grade student. Then they focus on children's understanding of place value and, in the last part of the class, on children's understanding of rational numbers. After each interview, the instructor leads a class discussion focusing upon what the PSTs learned, struggled with, or found surprising during their interviews. The interview sessions are interwoven with content discussions, in which some points are illustrated by using video clips.

The individual interviews and tutoring sessions, accompanied by reflections on the experiences, motivate the PSTs and help them to see that mathematics is a complex subject to teach and to learn. When they see, firsthand, a child struggle to make sense of some of the ideas and then see children on video clips struggle with the same ideas, they begin to recognize the difficulty of the topic and realize that it merits their attention. We hope that this compelling evidence shapes their beliefs and ultimately motivates them to attend to the mathematical content.

### **What Evidence Do We Have to Support a Focus on Children's Mathematical Thinking?**

#### **Research Design**

The data described in this section comprise a subset of the data collected as part of a large-scale study involving five treatments and 164 PSTs. The study was conducted in Fall 2001. The description of *all* treatments and data collected is beyond the scope of this paper, and because of the project timeline, the analysis provided here is preliminary. We do, however, provide evidence that the CMTE-L did shape the PSTs' conceptions about mathematics and mathematics teaching and learning, and did so to a greater degree than other treatments.

#### **Data Sources**

To investigate the CMTE-L's effects on PSTs' beliefs about mathematics and children's thinking, we analyzed data from several sources. One source was an open-ended-response computer survey designed to assess PSTs' conceptions about seven beliefs related to mathematics and children's mathematical thinking. Each belief was measured by at least two items; the scores for the items were merged, and a single score was assigned for each belief. The blinded data were coded by trained coders

external to the project. The inter-rater reliability for the coded data averaged 84%. Coders resolved disagreements through discussion of the data as related to the scoring rubric. We discuss change data, representative of the magnitude of change scores on all beliefs from pretest to posttest, for one belief: *The ways children think about mathematics are generally different from the ways adults would expect them to think about mathematics (Belief 7)*. Both during and after the semester, we interviewed small numbers of PSTs individually and in groups. We have also used end-of-course written-survey data to triangulate the results.

### Sample and Treatments

All project participants were paid and were randomly assigned to one of five treatments. We limit this analysis to two treatments, the CMTE-L ( $n = 50$ ) and an early field experience, the Mathematical Observation and Reflection Experience in a Reform Classroom (MORE-R<sup>3</sup>,  $n = 22$ ). PSTs who engaged in the MORE-R observed mathematics lessons of teachers known to engage in reform-teaching practices. We compared the data for PSTs in these two groups for two reasons: (a) The MORE-R provided PSTs access to children in classrooms of reform-oriented teachers, and so one might expect that the conceptions about children's mathematical thinking and mathematics would be shaped more positively for the MORE-R PSTs than for the CMTE-L PSTs, and (b) sending PSTs to schools to observe is a common early teaching-related experience for PSTs; thus, we compare a more typical model to the proposed one. We consider the MORE-R an enhancement from the typical field experience in that teachers were carefully selected and known by project team members to engage in aspects of reform-oriented mathematics teaching.

### Data Analysis

To give a sense for the magnitude of the change in CMTE-L students' conceptions, we provide data about one belief, stated above, on children's thinking. This belief was measured by three items, one of which follows.

- a) Which fraction is larger,  $1/5$  or  $1/8$ , or are they the same size?
- b) Your friend Jake attends a birthday party at which there are five guests who equally share a very large chocolate bar for dessert. You attend a different birthday party at which there are eight guests who equally share a chocolate bar exactly the same size as the chocolate bar shared at the party Jake attended. Did Jake get more candy bar, did you get more candy bar, or did you and Jake each get the same amount of candy bar?

Which of these two problems is easier for children?

\_\_\_  $a$  is easier than  $b$

\_\_\_  $b$  is easier than  $a$

\_\_Both items are equally difficult.

Please explain your answer.

This item is intended to measure PSTs' beliefs about whether real-world contexts support or hinder children's thinking. Many adults believe that children are best supported in their mathematical thinking by working primarily with symbols, but evidence shows that real-world contexts better support children's thinking (Carpenter et al, 1999). To receive the highest score on this item, a respondent would select the choice *b is easier than a* and explain that the real-world context supports children's thinking whereas the symbols may actually interfere. On the pretest, 74% of CMTE-L and MORE-R PSTs received the lowest score possible on this item, indicating a belief that solving word problems is more challenging for children than interpreting symbols. One PST wrote, "Story problems tend to get children confused and allow mix ups to happen." That PSTs initially hold this belief is hardly surprising; during CMTE-L class discussions, many acknowledged their own difficulties in solving word problems and did not think that experiences with contexts could help young children to make sense of mathematics. Only after interviewing young children and seeing them solve a variety of problems in context did some of the CMTE-L PSTs begin to think differently about how children might come to understand mathematics.

## Results

Across all seven beliefs measured, more CMTE-L PSTs than MORE-R PSTs increased their belief scores: More than 2/3 of the CMTE-L PSTs' belief scores but fewer than 1/2 of the MORE-R PSTs' belief scores increased. Furthermore, the CMTE-L PSTs' increases were greater than those of the MORE-R PSTs. For Belief 7, 67% of the CMTE-L PSTs' belief scores increased at least 1 point (on a 5-point scale), compared with 52% of the MORE-R PSTs' scores. The percentage of CMTE-L PSTs' scores that increased at least 2 points (36.7%) was more than 1 1/2 times the percentage of MORE-R PSTs' scores (23.8%) that did so, and the ratio was even greater for those whose scores increased 3 points: 12.2% of CMTE-L PSTs' scores increased 3 points, 2 1/2 times the percentage of such MORE-R PSTs' scores (4.8%).

One CMTE-L PST who on the pretest received the lowest score on the item above, received a high score on the posttest by responding, "[Choice *a*] might get confusing for kids because...they might think that since 8 is bigger than 5 then [1/8] is the bigger of the two numbers. ...[Choice *b*] is easier because it is put into real life context. This way the child will be able to think about himself being at the party and be able to know which one is larger."

We hypothesize that the CMTE-L PSTs' greater improvement compared with MORE-R PSTs' can be accounted for because the CMTE-L PSTs worked, in principled ways, directly with one child at a time. This experience was motivating, both because they worked with a child about whom they cared and because they had to be

prepared to elicit, understand, and support the child's mathematical thinking. Furthermore, the CMTE-L PSTs had opportunities to debrief their interviews and hear from classmates about their experiences working with children. The instructors attempted to focus these discussions on typical, interesting, or puzzling thinking that children exhibited. Through the thinking of the children, the instructors could engage the PSTs in discussions about mathematics. This combination of experiences influenced the beliefs of more than 2/3 of the CMTE-L PSTs.

Although the MORE-R PSTs' belief scores improved, both the number of PSTs who changed and the extent of change were less dramatic than for the CMTE-L PSTs. For some readers this result may seem surprising inasmuch as the PSTs visited classrooms, observed reform-oriented teachers, and reflected on their experiences in written form after each observation. However, this model has limitations. For instance, although the selected teachers were known to engage in reform-oriented teaching practices, such teaching is multifaceted, and some teachers may have exhibited fewer of its features than others. Also, classrooms have many aspects, so that for PSTs to focus primarily on children's mathematical thinking is challenging. Other than considering the mathematics of the learner, MORE-R PSTs could focus on, for example, classroom management, manipulative selection, personality of the teacher, bulletin boards, arrangement of desks, textbook use, and so on. Thus for PSTs to focus on our objective, children's mathematical thinking, was difficult. In contrast, in the CMTE-L the focus on children's thinking was explicit, and tasks and video clips were constrained with that focus.

Although not all students who participated in the CMTE-L greatly improved their belief scores, 95.7% of the CMTE-L PSTs described the experience as either *very valuable* or *valuable*. The CMTE-L PSTs whose belief scores did not improve much may have enjoyed and valued the experience of working with children but may not have shifted this appreciation to mathematics and children's thinking. What experiences could have supported these PSTs to change? is an open question.

### Conclusion

When our PSTs worked with children and attempted to analyze their mathematical thinking, most came to see that children can approach mathematics in a variety of creative and nontraditional ways and that children must build upon an understanding of fundamental, underlying concepts. The PSTs thus began to view mathematics as a web of interrelated concepts and procedures, and they recognized that children could solve problems in ways that were different from adults' ways. With this understanding, many PSTs came to care about mathematics, not as a discipline of intrinsic interest but as a means to enable them to complete their caring relationship with a child engaged in mathematical thinking. Near the end of the CMTE-L, a student commented on this change in attitude:

I can't even explain in half of a page how much my views have been affected. When I worked at elementary schools [while] in high school, I never understood why the kids did not get what I was saying. I can't wait to go back [to my mom's classroom] and help the kids with math. I am so much more confident in my understanding of math. I have a greater appreciation for math ... now. I get worried just thinking about how I am going to make my kids *really* understand place value and math. Instead of dreading teaching math, I am now really excited (and nervous) about teaching math. (Jackie, 12/05/01)

In this paper we provided a framework to explain how we sought to address the problem that the study of mathematics content is separated from and precedes the study of pedagogy for undergraduate PSTs. We integrate mathematics content and pedagogy earlier for PSTs by building upon the interests that drew PSTs to teaching: interest in children. Our initial data are promising. These deliberately chosen and highly structured experiences in the CMTE-L support PSTs' engagement in and motivation to learn mathematics to prepare them to support their future students' mathematical thinking.

### Notes

<sup>1</sup>Preparation of this paper was supported by a grant from the National Science Foundation (NSF) (REC-9979902). The views expressed are those of the authors and do not necessarily reflect the views of NSF.

<sup>2</sup> The Children's Mathematical Thinking Experience—Live (CMTE-L) stands in contrast to a separate treatment, the Children's Mathematical Thinking Experience—Vicarious (CMTE-V). In the CMTE-V, students watch video clips of children solving mathematics problems, but do not work directly with children.

<sup>3</sup> The Mathematical Observation and Reflection Experience in a Reform Classroom (MORE-R) stands in contrast to a separate treatment, the Mathematical Observation and Reflection Experience in a Traditional Classroom (MORE-T).

In the project described in this paper, the synthesis of research into situated learning was used to design and develop a multimedia learning environment to teach assessment strategies in mathematics to preservice teachers which was intended to transfer to teaching practice. The paper describes a follow-up study which investigated the influence of using the authentic approaches presented in the multimedia learning environment on the teaching and assessment practices of the same people as beginning teachers. Practicing teachers, who as preservice teachers participated in the earlier study, were interviewed with regard to the influence that the authentic approach had on their first and second years of teaching and assessing mathematics. Analysis of data indicates that a complex mix of influences and environmental factors impact upon the teachers' use of assessment strategies in their beginning years of teaching, and that preservice pedagogical beliefs are not always translated to beginning classroom practice.

### **Introduction**

The persistent failure of beginning teachers to access pedagogical skills and strategies acquired during teacher training is an ongoing problem for teacher educators throughout the world. In mathematics, despite the variety of strategies recommended, the *Third International Mathematics and Science Study* indicated that teachers generally continue to limit their approaches to traditional methods (Lokan, Ford & Greenwood, 1996). Traditional classroom approaches reflect a view of mathematics as a set of discrete, hierarchically arranged facts and skills; a view of learning mathematics as replication and repetition; a view of teaching mathematics as exposition and practice; and a view of assessing mathematics as paper and pencil testing for the sole purpose of grading and ranking (Niss, 1993; Stephens, 1992). This lack of progress may result from ineffective teacher-training courses (Borko, et al., 1992). Even newly-trained teachers with non-traditional beliefs about mathematics teaching and learning return to traditional teaching approaches (Brown & Borko, 1992; Raymond, 1997).

One reason for the long-term ineffective practical outcomes of such university courses, is according to Resnick (1987), a result of too little engagement with genuine situations, and too much emphasis on theoretical perspectives. Genuine situations such as school practice, may enable some student teachers to experience classrooms which reflect curriculum reform. For many, however, their school practicum experience is often a reaffirmation of the traditional approaches that are already ingrained from their

own schooling (Comiti & Ball, 1996). For those who do observe and engage with teachers using current approaches, the extent and range of approaches seen is limited to a few—the ones with which their supervising teachers are familiar and comfortable implementing. One way to align university teaching and learning more substantially with the way learning is achieved in real-life settings is to base instructional methods on more recent theories of learning which reflect this shift, such as *situated learning* (e.g., Brown, Collins, & Duguid, 1989; Collins, Brown, & Newman, 1989; Lave & Wenger, 1991; McLellan, 1996). Collins (1988) defines situated learning as: ‘the notion of learning knowledge and skills in contexts that reflect the way the knowledge will be useful in real life’ (p. 2).

Nine critical characteristics of situated learning environments were defined from the extensive literature on the subject and used to inform the instructional design of learning environments (described in detail in Herrington & Oliver, 2000). The learning environment, in reflecting a situated learning approach, needed to:

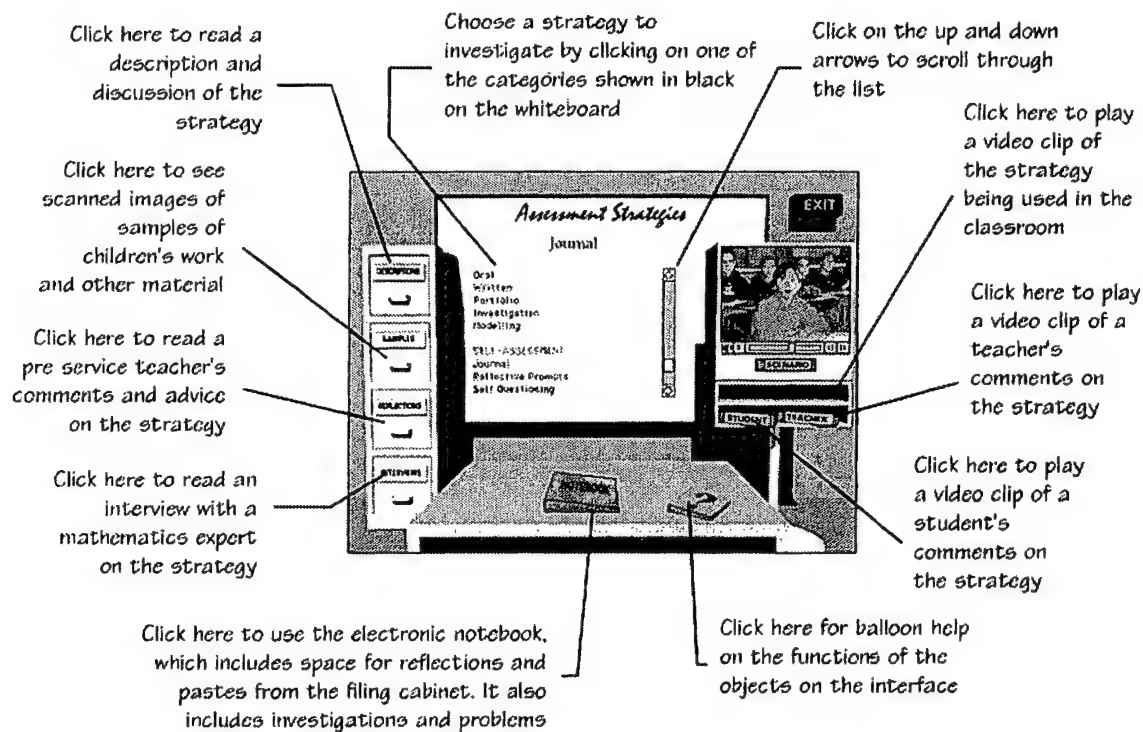

- provide an authentic context that reflects the way the knowledge will be used in real-life;
- provide authentic activities;
- provide access to expert performances and the modelling of processes;
- provide multiple roles and perspectives;
- support collaborative construction of knowledge;
- provide coaching and scaffolding at critical times;
- promote reflection to enable abstractions to be formed;
- promote articulation to enable tacit knowledge to be made explicit; and
- provide for integrated assessment of learning.

A multimedia program was developed to enable teachers and pre-service teachers of mathematics to explore issues of assessment, entitled *Investigating Assessment Strategies in Mathematics Classrooms* (Herrington, Sparrow, Herrington, & Oliver, 1997). Twenty three assessment strategies suitable for use in K-12 classrooms were identified and grouped in the following categories: *Questioning*, *Interviewing*, *Testing*, *Problem solving*, *Reporting* and *Self-assessment*, and presented in a multimedia format. Five complex, authentic activities were designed consisting of memos and other documents, to enable students to explore the resource within the parameters and constraints of a realistic task. The interface (see Figure 1) simulates the front part of a classroom with the resources represented by appropriate metaphors (such as video cassettes, filing cabinet drawers, folders on the desk) giving direct access to the following resources:

- 1) Video clips of teachers using various assessment techniques
- 2) Video clips of teachers’ comments on the strategies

- 3) Video clips of children's comments on the strategies to present their own thoughts
- 4) Interviews with experts in the field to provide theoretical perspectives
- 5) Reflections by third year preservice teachers to provide practical advice
- 6) Text descriptions of each assessment category
- 7) Teachers' resources and children's work samples
- 8) An electronic notebook to enable students to copy text and to write their own ideas
- 9) Problems and investigations to enable the students to complete authentic tasks.

**Figure 1.** The interface of *Investigating Assessment Strategies in Mathematics Classrooms* showing constitutive elements.

In the first study, preservice teachers explored a variety of assessment strategies appropriate to K-12 mathematics classrooms using the multimedia assessment program. The students spent three weeks of the semester examining strategies within the context of a complex and sustained authentic activity, where in small collaborative groups, they prepared and presented a report on a new assessment plan for mathematics in a school. In order to do this, they were asked to consult with experts, look at what

was happening in classrooms, talk to teachers, talk to students and so on—all of which could be done ‘virtually’ from the CD-ROM.

Three pairs of students were interviewed and observed as they used the multimedia program and the analysis of talk revealed that students used a substantial amount of higher-order thinking as they worked with the assessment program (reported in Herrington & Oliver, 1999). A study of the transfer of a variety of assessment strategies to classroom practice was conducted with the students as they completed two weeks professional practice in schools approximately five weeks after the completion of their work on the assessment program (reported in Herrington, Herrington, & Sparrow, 2000). All the students were required to teach mathematics classes in this practice, and it was expected that they would have the opportunity to implement different assessment strategies. Both students and supervising teachers in the schools were interviewed and the comments were transcribed and analyzed. Transfer was thought to have occurred if firstly, students using the interactive multimedia program on assessment had a good understanding of the types of assessment appropriate in the mathematics classroom and were able to articulate this understanding; and secondly, they employed a variety of the assessment techniques shown in the program, as opposed to the predominant use of pencil-and-paper tests (Cognition and Technology Group at Vanderbilt, 1993).

Analysis of the data shows that all the students could speak knowledgeably and confidently about assessment, and all the students used a variety of techniques to assess children’s understanding. As was expected, all were influenced strongly by the supervising teacher in the schools, many of whom had planned assessment in advance of the students’ arrival. However, even when assessments had been planned in advance, all students used techniques that they were able to use without the contribution or agreement of the supervising teacher—such as checklists, anecdotal records and open interviews, which students could use individually with children as they circulated around classrooms. Five of the six students attributed their use of assessment techniques directly to the interactive multimedia program.

These very positive findings were qualified by two mitigating factors: the brevity of a two week professional practice and the substantial influence of the supervising teacher. In the words of one student: “I’m not the qualified teacher. I’m in their situation, in their room, conforming to their rules. So I can’t just suddenly say ‘Hey, let’s do some oral assessment’”.

Many of the students in the first study were inhibited in the choice of assessment strategies by the influence and authority of their supervising teachers, in a way which may not have been an issue if the students were practising teachers with their own classes. In order to investigate this issue further, a follow-up study of those students who had gained employment was carried out when the students were in the second year of teaching.

In the follow up study reported here, interviews were conducted with students from the first study who had gained employment as teachers. These four teachers were

in their second year of teaching, three in secondary schools Evie, Rowan and Zoe (pseudonyms used) and one in a primary school, Debra. Three teachers (two female, one male) were teaching mathematics in private schools in the metropolitan area of Perth, and one female, Evie, was teaching in a remote outback Government school in the north of Western Australia.

Participants were interviewed at their schools, for approximately 90-120 minutes each using an interview protocol described by Denzin (1989) as *a non-scheduled standardized interview*. Questions and probes were determined in advance, but there was flexibility in adjusting the interview protocol. Students were questioned about: their beliefs about assessment; their knowledge and use of assessment strategies in mathematics; the influence of school policy, colleagues, and national guidelines on their assessment practices; and the influence of their teacher training on their current practices. The interviews were recorded and transcribed for analysis. Transcripts of interviews were analyzed using techniques of qualitative analysis recommended by Miles and Huberman (1994) and Eisner (1991). Transcripts were summarized for each student and placed in a matrix that allowed comparisons to be made for each student's response to each interview question. A further summary of these responses is given below.

## Results

### Beliefs About Assessment

The secondary teachers felt that generally assessment practices had changed since they were at school with more emphasis on problem solving, investigations, and project work. Evie believed that many students had difficulties in adapting to different types of assessment, particularly those students that lacked motivation and showed poor attendance. She noted that open book exams had become a common practice at her school.

Zoe felt that the use of graphing calculators resulted in more conceptually based questions and was concerned about the lack of reliability of tests and grading. Rowan commented that there was too much testing in his school and would like to see more of an emphasis on investigations and problem solving with younger students.

Debra, a year one primary school teacher, enjoyed the use of varied approaches to understanding students and felt that there was less use of worksheets than when she had gone to school. She believed her assessment to be diagnostic identifying areas where individual children needed assistance.

### Self Reported Assessment Practices

Two secondary teachers, Rowan and Zoe, reported that testing was used as their main form of assessment, ranging from multiple choice tests to conceptual tests using graphics calculators. They also indicated that they used group projects, posters and oral reports. The two other teachers, Evie and Debra, reported on using tests, observa-

tions, checklists, portfolios, projects and individual interviews. Debra and Rowan had used self assessment techniques where children reflected on their learning by drawing faces to express their understanding and by making review sheets for exams. Zoe indicated that she had tried using journals but found them unsuccessful because students found it difficult to give thoughtful reflections.

### **Perceived Influences on Assessment Practices**

Debra relied heavily on the advice of a more experienced teacher and support from the Principal. Evie also felt that advice from colleagues was more helpful than professional development organized by the district office.

Zoe attributed her assessment approaches to mathematics education courses completed at university. However, the school had a policy of encouraging similar assessment strategies across grade levels which she indicated limited her use of alternative approaches.

All the teachers recalled having used the interactive multimedia in their mathematics education course and felt that it was a helpful and important resource – one with which they were able to learn about different forms of assessment in a collaborative and enjoyable way. Debra, in particular, felt that she would be able to find good use for the program now that she is teaching.

### **Discussion**

In both studies the teachers appeared to have a sound understanding of alternative assessment strategies and ways in which they could be implemented. While the first study presented constraints in employing these strategies on professional practice, (such as limited time and the influence of the supervising teacher), as teachers they were also faced with cultural and practical constraints. Constraints include the requirements of the mathematics department in the school, State Curriculum guidelines, issues of practical classroom management, personal issues such as the amount of time that can be devoted to planning, and convictions about the suitability of certain types of assessment for certain students. As such, the teachers' pedagogical beliefs do not always translate to classroom practice.

Analysis of data indicates that a complex mix of influences and environmental factors impact upon the teachers' use of assessment strategies in their beginning teaching. For example, Zoe commenting on her practicum supervising teacher's use of assessment strategies in 1996, appeared to have a range of alternative strategies in mind which she failed to use in her teaching practice in 2000:

*Interview with Zoe (1996):* It's opened my eyes a lot more ... and also watching my [supervising] teacher and really disagreeing with a lot of the assessment strategies he'd use. He only used pencil and paper assessment strategies. Of course I didn't say anything, but I'd sit there thinking 'Oh remember what we learnt'.

*Interview with Zoe (2000):* Testing. That's the main approach. With years 8, 9 and 10 mainly topic testing, and then at the end of their year we do an exam to get them ready for Year 11 and 12 ... If you put it on a piece of paper, you know if they can interpret it. I don't think that sort of testing is fantastic for every student ... but I can't think of another really appropriate assessment task.

The enthusiasm Evie had in 1996 to try a range of assessment strategies in her own classes, by 2000 had been overwhelmed by significant social and cultural problems:

*Interview with Evie (1996):* There were only limited types of assessment that I could use [on teaching practicum], but hopefully in the future I'll be able to use a wider range of the ones that were on the multimedia. Hopefully I'll be able to ... start journals and things like that.

*Interview with Evie (2000):* I'd like to vary a lot of things, such as I'd like to do a lot more collaborative work with the kids, group work. And probably even presentation type stuff, where kids can actually demonstrate or explain their findings, whether it be an investigation or even project work ... I just find that all these fantastic ideas that I come up with usually seem to back-fire when I use them in the classroom. I don't see myself as being a really boring teacher ... [and] I'm not blaming it on the kids—but they just lack any self-motivation. And it's not just me ... all the learning areas are having the same problems with the same kids. I think the problem is they don't see the importance of education ... there is a high rate of kids dropping out, and girls falling pregnant at a young age which is really sad.

While the teachers' pedagogical beliefs do not always translate to classroom practice, this is not to conclude that teachers' beliefs about assessment revert to traditional beliefs. All the teachers in the study, when prompted on various assessment strategies indicated they had tried alternative approaches and that they would be willing to try these techniques in the future. One teacher indicated that she would try journals as an assessment strategy when she could better explain to the students how to keep them. The use of a situated learning environment (such as that provided on the CD-ROM) during teacher training may provide contextualised knowledge about assessment strategies but this knowledge will not necessarily be applied in teaching practice either as preservice or novice teachers because of intervening constraints. The scenarios aimed at developing pedagogical knowledge but did not directly focus on potential constraints that needed to be taken into account. This could be overcome by including these aspects as part of the problem that needed consideration, and could equally well be evident as teacher guidance when the student teachers discussed their solutions to the scenarios.

The apparently powerful social, cultural and environmental pressures with which new teachers must deal—pressures which cause many to revert to more traditional modes of teaching to deal with them— could also arguably be ameliorated by providing ongoing professional development. The professional development of beginning teachers is recognized as a necessary process in the long-term development of ‘full-fledged professionals’ (Schoenfeld, 2002, p. 22). Without support, these teachers can find it difficult to adapt to change, and can readily abandon approaches to teaching and learning emphasized in their university courses and current curriculum initiatives (Schoenfeld, 2002).

However, such support needs to be focussed. It is apparent the teachers in this study retained their pedagogical beliefs and practices that they had learnt during their university mathematics education course using the multimedia but were often constrained in applying this knowledge in the initial teaching environment. Professional development that simply revisits approaches encountered at university may well be ineffective because it does not address the range of constraints that are faced by novice teachers. On the other hand, novice teachers may benefit from support in *constraint management* where the problems of novice teachers could be aired and discussed in a similar way that could happen with preservice teachers. Rather than face to face discussion of potential problems, the Internet has the potential for providing a forum where constraints could be openly discussed and resolutions reached in a collegial environment.

### Conclusion

The studies described in this paper have revealed an ongoing discrepancy between the preparation of teachers and the reality and demands of classroom teaching. The use of situated learning environments has gone a long way towards ameliorating the cognitive gap between theory and practice, but it has not been entirely successful (on its own) in promoting sustained transfer to the real teaching situation. Practical constraints and real-life restrictions on teachers’ practice need to be accounted for more substantially and incorporated more fully into the situated learning model. Further research on these factors, and inservice professional development as described here, may help to ensure that pedagogically sound practice is learned, applied and sustained throughout teachers’ professional life.

# **MATHEMATICIANS' PERSPECTIVES ON THE MATHEMATICAL KNOWLEDGE NEEDED BY ELEMENTARY PRESERVICE TEACHERS**

LouAnn H. Lovin  
James Madison University  
lovinla@jmu.edu

This study explored what two mathematicians believe elementary preservice teachers need to learn in mathematics courses to enable them to be effective teachers of mathematics. The participants used the word "knowledge" not to mean particular facts or identifiable pieces of information, but a more global sense of the subject and how one thinks about and learns mathematics. Three major themes emerged from the data. These mathematicians strived for their preservice teachers to be life-long learners of mathematics; to think about mathematics as a creative process; and to start with definitions and axioms to obtain the first two goals. Implications for practice and future research are discussed.

## **Purpose of Study**

It sometimes seems that mathematicians and mathematics educators are at war about what preservice teachers need in terms of mathematical content. As Judith Sowder (2000) highlighted in her address at the NCTM research pre-session, to circumvent a war requires that both sides "come to understand and respect the value system of the 'other' side" (pp. 2-3). Such was the purpose of this exploratory study, to investigate what mathematicians see as crucial for preservice teachers to learn in content courses in an effort to understand what is valued by mathematicians. Given this understanding, mathematics educators have a better chance of seeing how our perspectives can fit with, and not fight against, the "other side."

## **Theoretical Perspective and Related Literature**

Research suggests that a teacher's view of mathematics has a direct impact on how the subject is taught (Thompson, 1992). There have been numerous studies about the beliefs held by elementary, middle school, and secondary classroom and preservice teachers about mathematics and the teaching and learning of mathematics. This study investigated mathematicians' viewpoints about what preservice teachers need to learn in mathematics courses. Consequently, this paper focuses on a group of mathematics teachers that largely has been ignored in the past: college mathematics professors who contribute to preservice teachers' understanding of mathematics and indirectly to their understanding of mathematics teaching and learning.

The discussion regarding the mathematical knowledge and preparation of teachers has gone on for quite some time. Back in the 1960's, the movement was to enhance teachers' and students' knowledge of set theory. Deborah Ball (1990a; 1990b) identified shortcomings in preservice elementary and secondary teachers' mathematical

knowledge. Borko, et al. (1993) found that an elementary preservice teacher who had a stronger mathematics background than most elementary preservice teachers was still lacking in the knowledge needed to effectively teach elementary school mathematics. Liping Ma's (1999) work has awakened many to the idea that the type of mathematical knowledge needed for K-12 teachers might be a blend of content knowledge and pedagogical knowledge. In fact, the American Mathematical Society [AMS] in cooperation with the Mathematical Association of America [MAA] has published a report that calls for a "rethinking of the mathematical education of prospective teachers within mathematical sciences departments at U.S. two- and four-year colleges and universities" (CBMS, 2001, p. 4). In particular, the report highlights that many mathematicians see aspects of mathematical knowledge for teaching as content for methods courses while education faculty see these aspects as fundamentally tied to mathematical content. As a result these issues are often overlooked. Consequently, it is argued in this document that it is "vital that faculty in the mathematics department and the school of education agree on substantial expectations for student learning and achievement in these mathematics courses" (p. 7).

The *Professional Standards for Teaching Mathematics* (National Council of Teachers of Mathematics [NCTM], 1991) suggests preservice teacher education should reflect the standards recommended for K-12 students. The standards proposed for K-12 students (i.e., *Principles and Standards*, NCTM, 2000) emphasize a balance between learning procedural and conceptual knowledge so that students have a more relational understanding (Skemp, 1978) of the mathematics being studied. But what do mathematicians believe preservice teachers need to learn in mathematics courses to enable them to be effective teachers of mathematics? What do they see as the "big ideas" in content courses for preservice teachers?

### **Methods and Data Sources**

The participants in the study were two mathematicians, M1 and M2, who teach content courses for elementary and middle school preservice teachers at a regional university in the south. The mathematics department at this university has a history of communicating and working with the mathematics educators in the education department. While we do not agree on every issue, there is the atmosphere of respect for other people's ideas. The program within which these mathematicians work is democratic in the sense that the people who will teach the same course decide as a group on the textbook that will be adopted for the course. They also decide on the specific topics that will be covered in the course. Nonetheless, in reality, the same course is usually very different depending on the professor and his/her emphases and teaching strategies.

The data were collected from two semi-structured interviews, numerous informal discussions, and classroom observations. One of the mathematicians, M2, also observed one of my methods courses during the same semester I observed his content

course. M2 also shared with me a dissertation written by Eyles (1998) at the University of Texas about a teaching approach M2 uses in his mathematics courses. This dissertation included a transcript of an interview with M2 about this approach to teaching mathematics.

The study was designed to investigate people's perspectives and not to test specific hypotheses, thus, a qualitative design was appropriate. Data collection and analyses were guided by analytical induction techniques (LeCompte & Preissle, 1993; Patton, 1990). I began the study by observing the mathematicians' classrooms and engaging in discussions with them afterwards about various episodes. I created the first interview protocol based on these observations and discussions. The interviews were transcribed and those along with the field notes from classroom observations were coded. As I began to analyze the data, themes and relationships began to immerge. In informal discussions in person or via e-mail, I was able to ask questions to help modify and clarify the hypotheses that were developing. The second interview centered on portions of *The Mathematical Education of Teachers* (CBMS, 2001), in particular, the chapters regarding recommendations for content courses for elementary preservice teachers.

### Results

The participants in this study were very genuine about their desire to improve mathematics education in schools by making an impact on their preservice teachers' knowledge of mathematics. They were convinced that what they were doing in the content courses would result in better teachers of mathematics at the K-8 levels. However, both were also quick to say that his way was not the *only* way to approach teaching mathematics to elementary preservice teachers. Both mathematicians gave overall favorable reviews of the CBMS document and were satisfied that what they were doing in these courses was in line with the document's recommendations. M2 explained,

When I read [the CBMS document], and then thought about what it is I do, it looks like I read this *before* I made my courses, in a sense, that many of the points in here, I claim are purposely addressed without knowing that those were actual initiatives, because of what I want to do to or for perspective students. (M2, interview)

Data indicated that these mathematicians strived for their preservice teachers to be life-long learners of mathematics; to think about mathematics as a creative process; and to start with definitions and axioms to obtain the first two goals.

These mathematicians wanted their students to see mathematics as a creative process, not a body of procedures to memorize:

I want them to see mathematics as a creative activity. I want them to see it as something that is different perhaps than what they may have come to believe it is. That it is not a collection of formulas and rules, but it is a way of reasoning and a way of thinking in attacking problems. (Interview, M1).

One day in class, as M1 reminded the students that he was expecting them to understand and explain why something was true, a student blurted out, “Are you an outcast among your colleagues?” (classroom observation). This student went on to explain that he could not fathom that this might be an acceptable thing to do in a mathematics class. The student was also frustrated that this was his last mathematics course and he was just now being asked to learn why.

When discussing students’ evaluation of the courses, M1 described that one of the complaints I get from the students is they’ll say, this was more critical thinking than what I need to do in the classroom or what I am going to teach or...they will say, this was too much reasoning. Fine, I figure I have been successful... until you do that, it is going to be procedure. And that is the message that has to get through to people who are going to teach.

How the mathematicians attempted to encourage their preservice teachers to think about mathematics as a creative process was very different. M1 posed problems that students had never seen before in an effort to encourage his students’ progress. If they were successful in taking what they knew and working on something novel, he was confident that they would begin to see that mathematics was about reasoning. M2’s teaching wholeheartedly supported this idea. His approach to teaching was based on the Moore Method, a method of teaching named after R. L. Moore of The University of Texas that resembles the Socratic method. In this approach, the teacher begins with certain axioms and the students build the mathematics from those axioms. Problems are posed and students are randomly called on to respond, with the expectation that other students in the class will listen carefully to their classmates’ responses and speak up if there are any mistakes made. In talking about his teaching approach, M2 maintained,

The issue is we identify some things as being central. And what mathematics is about is to find out what the consequences of those ideas are. And then succession is the whole game, what else has to be true. And these things are not something that are imposed on you, these are the things that you discover. That’s what the thinking is all about. (M2, interview)

The mathematicians believed that one of the most important aspects of their courses was to instill life-long learning of mathematics in their students. M2 emphasized that his students needed to develop “habits of mind” that would enable them to be life-long learners of mathematics. The premise behind this idea of life-long learning is that since preservice teachers cannot learn all the mathematics they will ever teach, they need to learn how to learn mathematics so that when they are confronted with content that they do not understand, they have the “mindset,” “habits of mind,” or strategies with which to figure it out. It is this very idea that these mathematicians argue is the creative process in mathematics – taking something that you do not know

and figuring it out with ideas that you do know.

I don't think the content is that important – if we presume that they know high school math.... I think there is a foundational level that you can get even through something like a [content course for preservice teachers] – by foundational, I mean this idea of definitions, axioms, applying definitions, developing things from *some* axiomatic process. The one I use is set theory. I take set theory as sort of the basis upon which we do everything in [the course]. And so, it doesn't matter what those bases are, as long as somehow there is a basis and from there you build. I think they need *that* experience. (Interview, M1)

This mathematician was not concerned about content knowledge, per se, but was more interested in the students becoming competent using definitions, axioms, and theorems to create something. In many of our discussions, he argued that if a student is capable, he/she should be taking calculus, not the mathematics courses for elementary preservice teachers. His perspective was on the *process* of doing mathematics.

In explaining why this emphasis would make these students good teachers of mathematics, he explained that:

When they teach mathematics, they will understand maybe the significance of what the definition does for a mathematician as opposed to someone else. For someone else, the definition might be a way to use a word, whereas for us, it's a way to build theory. The elemental definitions provide the links. So if you make them go all the way back to definition, then when they're teaching their kids, they will see what those connections are, see what the links are. (M1, interview)

He was convinced that if someone came through their calculus course, that they would be able to figure out any elementary mathematics because of the creative experiences they would have had in the calculus course.

Both mathematicians were adamant that these courses for elementary preservice teachers must be taught at a college-level, which meant using an axiomatic approach. M1 explained his developmental approach in which he allowed his students to use only the definitions that had been discussed in class to tackle problems. In explaining how he introduced the meaning of fraction, he said

The way we get to it is that it is a number that allows us to solve the equation  $Ax=1$  where  $A$  is an integer. We know that we have problems that come up where we have to solve that so the question is what is necessary in order to do that. (interview)

M2 claimed that mathematics “begins with facts and definitions” (interview). His teaching centered around formal logic and language, the “tools of the mathematician”

(course handout). While I sat in his class and listened to students hesitating to respond to his inquiry about “what is an existential quantification which is logically equivalent to: ‘It is not the case that (if  $x$  is a number, then  $x \cdot x > 1$ )’” (test item) and as they tried to use the formal language he had imposed on them, I wondered if the students really understood what it was that he was attempting to get them to do.

In explaining why he emphasizes formal logic in his courses, M2 argued that formal logic allows people to clearly communicate about the mathematics. He maintained that formal logic is of utmost important and thus must be placed at the forefront of the course so that he has ample opportunity to “teach it again and teach it again and teach it again” (interview).

### Discussion and Implications

It seems that these mathematicians may not be on the same page as many mathematics educators, but they may at least be in the same book. Two of the big ideas that these mathematicians identified seem to be consistent with what the “reform” is calling for – life-long learners and a realization that mathematics is based on reasoning. If mathematicians and mathematics educators can agree about the “big ideas,” at least that is a starting point.

It seems apparent that the mathematicians value reasoning and justification, but to focus so heavily on axioms seems to hinder many students’ development. If the axioms and definitions are not meaningful to students, what kind of foundation are they starting from and where will that allow them to go? What is imperative for teachers to develop is this habit of mind that working mathematicians possess – a propensity to figure things out given what they already know. However, the starting points need to be more meaningful to students. I contend that the definitions and axioms used by these mathematicians were perceived by many of the preservice teachers as arbitrary, artificial, and abstract. A class using an axiomatic approach seems nothing less than the “typical” mathematics class in which they do not understand what the teacher wants them to do so they memorize the material with very little understanding.

If an axiomatic approach in content courses for preservice teachers is non-negotiable, it could lead to a positive aspect if this approach is explicitly used to help these students become aware of their assumptions when they make a decision or cling to a belief in any realm. If preservice teachers understand this subtle reality of axioms, it might help them to see that mathematics is not a set body of rules and procedures that never changes and must be memorized as absolute truths.

It is clear that maintaining the status quo by continuing to teach traditional mathematics content courses will only continue the vicious cycle in which students develop only a shallow understanding of mathematics because their teachers hold a shallow understanding of the content. A significant idea that I walk away from these mathematicians with is that students need to *learn* to learn mathematics. With so many topics crammed into a traditional content course for preservice teachers, there is little time

for students to really *do* much mathematics. So instead of attempting to cover several topics in a quick and cursory fashion, why not design content courses around a few topics that can be and are explicitly related to school mathematics. In such an environment, there is time for students to engage in *doing* mathematics – something they need to do to understand that mathematics is something you do rather than something you memorize. The type of work that mathematicians do is foreign to most people because of most people's experiences in mathematics classes. Consequently, with fewer topics needing to be covered, it is more likely that students can develop an understanding of how to use definitions in mathematics and to begin to develop the habits of mind similar to working mathematicians.

These mathematicians argued that if elementary preservice teachers are capable of taking calculus or “higher level” mathematics courses, we should allow those courses to substitute for the content courses for elementary preservice teachers. If those courses developed the spirit of doing mathematics in these preservice teachers, I might agree with their contention. However, given the current environment in which teachers work, when will these teachers have the time to develop a deeper understanding of the content they are teaching? Why not address the issue of teaching preservice teachers to learn mathematics using content that is explicitly tied to the content they will be teaching?

As a result of the work between mathematics and mathematics education at this university, we have discussed a couple of options for these early mathematics courses. We have discussed the possibility of offering an educational seminar that runs concurrently with these earlier mathematics courses. These seminars would be designed to make explicit the connections between the mathematics content the preservice teachers are learning and the content they will be teaching. Because of the existing working relationship between mathematics and mathematics education, this could prove to be an effective compromise. The department has also planned to pilot textbook materials for the earlier mathematics courses for PreK-8 preservice teachers in which set theory is not used as the guiding framework and in which the course is a mixture of content knowledge and pedagogical content knowledge. Definitions are a mainstay in this curriculum, however, they are definitions that teachers use in teaching elementary topics and concepts. Thus, the definitions are likely to be meaningful as well as relevant to the preservice teachers.

The mathematicians in this study were pure mathematicians. A future study could explore the perspectives of applied mathematicians. Given that applied mathematicians begin with the physical experience and model physical phenomena, they may believe different starting points other than axioms are more appropriate for preservice teachers.

One thing that has become clear to me as a result of engaging in this exploratory study is that it is essential that mathematicians and mathematics educators become

allies. We must learn to work together in order to break the vicious cycle that limits the mathematical knowledge of our teachers and students.

# **ENHANCING TEACHER CANDIDATES' GEOMETRY UNDERSTANDINGS: COMBINING THE USE OF TECHNOLOGY, A CONCEPT DEVELOPMENT ACTIVITY, AND DISCOURSE**

Sheryl A. Maxwell  
The University of Memphis  
smaxwell@memphis.edu

Teacher candidates participated in a computer-based project designed to enhance their knowledge of geometrical terminology as they used a concept development activity. The aggregate findings as indicated in three case studies reveal that knowledge of the links between two-dimensional and three dimensional figures increased (a) when participants' recognized they were learners, (b) as participants actively engaged in a conceptual development activity, and (c) through peer discourse.

## **Background**

Historically, many K-8 teacher candidates have experienced limited exposure to geometry in their own K-12 schooling experiences (Usiskin, 1987). Fueled by these weakened mathematical experiences, they often lack conceptual understanding of the link between two- and three-dimensional geometrical figures. Consequently, these teacher candidates rely mostly on the real-world use of terms rather than on more precise mathematical definitions. Several complementary activities were designed to help alleviate these misconceptions and build conceptual understandings to strengthen their geometrical knowledge. The presenter will initiate session discussion regarding (a) the need for teacher candidates to correct misconceptions and enrich their understandings of geometry, (b) the use of computer programs as a tool of learning, (c) the significance of using a concept development activity to promote learning, and (d) the benefit of peer discourse in learning.

## **Purpose of the Research**

The purpose of the research conducted was to investigate the instructional strategies of using computer software combined with a conceptual development activity and discourse to help strengthen a teacher candidate's understanding of the links between two- and three-dimensional geometry and related geometrical terminology.

## **Theoretical Framework**

This investigation was guided by several compatible theories: (a) the constructivist learning design, (b) an adaptation of the learning cycle model, (c) the van Hiele model of geometric thought (NCTM, 1987), (d) Vygotsky's research involving guidance of good analyzing questions from a teacher (1994), and (e) the appropriate use of the computer as a tool of learning (Baker, 1997). The instructional strategies were influenced by the constructivist learning design (Knuth & Peressini, 2001). Within

this learning theory, learners make personal meanings as they create shared interpretation with others. The teacher-facilitator orchestrates classroom events that promoted exploration and examination of mathematical topics. The researcher who is a teacher educator modeled interactive teaching tactics that involved the teacher candidates actively constructing their knowledge in multiple ways (Cagnon & Collay, 2001). Since, the researcher was aware that much learning or construction of knowledge takes place through social interactions, the teacher candidates problem solved in pairs, verbalized their thinking, and capitalized on these social interactions.

Two headphones were connected to each of the five classroom computers so the teacher candidates could use the software, interacting through normal dialogue, without the audio portion of the CD-ROM being heard in the classroom setting. The other students were involved with other autonomous geometry activities. This format allowed the teacher educator/researcher to interact throughout the activity time frame with the pairs of teacher candidates at the computers as well as other groups doing compatible geometrical activities. She employed a variety of analyzing questions to prompt the teacher candidates to dialogue about their understandings. The questions and the learners' comments as well as paired dialogues were captured on audio tape recorders located at each computer.

The learning cycle model (Atkin & Karplus, 1962) was originally comprised of a three-step cycle (a) exploration, (b) conceptual introduction, and (c) concept application. The adapted model, shown in figure 1, was designed to enable the teachers candidates to formulate and test new geometrical knowledge by incorporating computer software (Maxwell, 1999). By implementing the four components of *explore*, *specu-*

Figure 1. Conceptual Learning Cycle (Maxwell, 1999).

*late, assess, and generalize*, the math educator hoped that the teacher candidates could increase their conceptual understandings about geometry.

Elementary school teacher candidates should involve their future students in informal geometry during the elementary and middle school years. However, since teacher candidates have been instructed through rote memorization, they need to improve their spatial understandings of geometry prior to teaching concepts. According to Clements and Battista, "Spatial reasoning . . . consists of the set of cognitive processes by which mental representations for spatial objects, relationships, and transformations are constructed and manipulated" (Clements & Battista, 1992, p. 420). The geometry component was guided by the van Hiele model of geometry thought research that confirms that distinct levels describe students' geometrical conceptual development from elementary school to college (NCTM, 1988). The van Hieles' believed that progressions through the five levels could be achieved through carefully guided experiences (NCTM, 1987). Elementary /middle school students were to progress through the first three levels under the guidance of their knowledgeable teachers.

**Table 1.** The Van Hiele Model of Geometric Thought (Hatfield, 2000).

| LEVELS                           | CHARACTERISTIC   | 3-DIMENSIONAL EXAMPLES   |
|----------------------------------|--|--|
| <b>Level 0<br/>Visualization</b> | Student reasons about visual whole, recognizing the figure.                  | Student can identify a <i>cube</i> , <i>prism</i> , <i>pyramid</i> , and other three-dimensional figures.  |
| <b>Level 1<br/>Analysis</b>      | Student reasons about an informal analysis of the parts or attributes.       | Student identifies <i>face</i> and <i>non-face</i> , the shape of the <i>face</i> , can count the <i>edges</i> of a three-dimensional figure.    |
| <b>Level 2<br/>Abstraction</b>   | Student can form abstract definitions. Shapes can be related to one another. | Student can tell the differences between a <i>pyramid</i> and a <i>prism</i> through analysis of parts. Student can create a definition of each. |
| <b>Level 3<br/>Deduction</b>     | Student reasons formally within the context of a mathematical system.        | Student proves theorems about two- and three-dimension figures   |
| <b>Level 4<br/>Rigor</b>         | Student compares systems based on different axioms.                          | Student studies in absence of concrete models, sees abstractness   |

In this experience teacher candidates viewed two-dimensional *nets* and manipulated three-dimensional figures to help them learn about the links between two- and three-dimensional models. Later they define a *prism* through accomplishing a concept development activity. By using the computer as a tool of learning, the teacher candidates could develop their own cognitive understandings (Baker, 1997).

### Research Design

This study was conducted using qualitative methods. The researcher determined that the naturalistic classroom setting of teacher candidates experiencing cognitive dissonance and beneficial discourse with completing a concept development activity might help to increase geometrical knowledge. The following research questions were addressed:

1. What happens to teacher candidates' understandings of the relationship between two-dimensional and three-dimensional geometric figures as they interact with peers, use the computer as a tool of learning, and complete a concept development activity?
2. By using a computer employing an experiential approach, can teacher candidates strengthen their conceptual understandings of two- and three-dimensional geometry?
3. As teacher candidates interact with peers and note misconceptions, what part does attitude play toward learning more about geometry?
4. Frequently, teacher candidates are confused by multiple meaning words as they grapple with understandings of concepts previously misunderstood. How do multiple meaning words influence their geometrical understanding of figures?

The study site was a purposefully selected mathematics methods class with five computers located in a classroom of a university in the Mid-Southern United States. In this study, forty teacher candidates from two K-8 mathematics methods classrooms participated in a computer-base project.

During two consecutive, three-hour, mathematics methods classes, pairs of teacher candidates were challenged to complete a self-sustaining activity guide containing prompting questions with an imbedded concept development activity. This concept development activity lasting one-hour was developed by a mathematics educator/researcher to increase the students' comprehension of the link between two- and three-dimensional figures. This activity incorporates a progression of a four cyclic strategy: exploration, speculation, assessment, and generalization through an interactive approach. Ultimately, the pairs of teacher candidates were to define a prism using the attributes discovered. The teacher candidates were briefly introduced to three-dimensional items in order to become aware of the various multiple-meaning words such as *face* and *net*. The teacher candidate pairs rotated to the computers as

vacancies occurred, while other groups of teacher candidates participated in compatible geometry activities (Hatfield, Edwards, Bitter & Morrow, 2000). Audio recorders were placed at each computer; two earphone headsets were connected to each computer. Teacher candidates used the CD-ROM software product entitled *Might Math™*, by EdMark® (1995), as a tool of learning. The superhero theme in the *Mighty Math™* software designed for elementary and middle school children teaches concepts connecting two- and three-dimensional geometry. Learners can learn terminology by experiencing what that terminology means. By manipulating the geometric figures through the use of the program, the learner can see geometry from a holistic point of view, as opposed to the frequently memorized definitions. The concept development activity *Prism Priming* guides learners of any age to recognize patterns that can lead to understandings.

### **Data Sources**

Data were collected from four sources: teacher candidates' written answers to various prompts as recorded on the activity sheets and quizzes, audio tapes of their active computer experiences and discussions, teacher candidates' extemporaneous writings located on journals/papers, and the teacher educator's field notes and documented responses to questions. Data were analyzed through constant comparative methods using grounded theory. The researcher used pseudonyms to provide anonymity to the teacher candidates as the case studies were developed. The teacher candidates' reactions to learning experiences conformed to one of three categories: floundering, gaining competence, and refining concepts. Although the three cases represent a slight amount of aggregate responses, the primary basis of each case was one teacher candidate of each category.

### **Three Case Studies**

The elementary/middle grade teacher candidates were apprehensive as we talked about their understandings of elementary geometry. Their prior experiences had been filled with anxiety, particularly as they tried to make sense out of the plethora of definitions, postulates, and theorems. Several learners admitted that geometry seemed like a blur, while others indicated it was a nightmare experience that they really wanted to dismiss. Timidly, a small minority acknowledged they had never had a formal course in geometry. Only a meager number of teacher candidates recognized geometry's importance to understanding mathematics more completely. However, the teacher candidates wanted to avoid this important mathematics subject. As they sat at the tables with their peers, they chatted nervously, dreading the impending activity.

### **Adventure Preparation**

Θ<sub>1</sub>: Diedre Nowell cocked her head in a distinctive manner, chatting to her friend and confidant, Sherry Mix. This course was just one more in her quest to become a

teacher. She assumed that if she exercised her normal charming mannerism, she would succeed. After all, this was just one course in a series that marked her progression in the Master of Arts of Teaching (MAT) degree designed for second career individuals. She believed she would accomplish some amount of understanding and be closer to her goal. Although her lack of knowledge of mathematics content troubled her somewhat, she internally hoped she had an acceptable knowledge of geometry, especially to teach elementary students. She would grin and bear this experience, hopefully getting help from her best friend, Sherry.

$\Theta_2$ : Bobbie Canard glanced at the other five women at her table. She believed that they all knew so much more than she did. The others laughed and commented to one another while she sat quietly, contemplating what little she knew. GEOMETRY—the word frightened her! In fact, math in general frightened her! Bobbie had contemplated that taking this math methods class with her friends would be helpful. Now, she was having doubts. She judged that they might find out how inept she was at math. She hadn't told anyone that she still had to complete a math deficiency in her undergraduate program—It was her secret! If she could just *hang on* to complete this class.

$\Theta_3$ : Vicki Stevens quietly listened to the discussion. She reflected about her understanding of geometry—she couldn't even recall any positive aspects about the subject, just lots of memory work. Learning had always come fairly easily to Vicki. However, now she questioned if she had really learned much of anything except various procedures. Nevertheless, she was willing to try various aspects of this course, just hoping that she could deepen her understanding of the math topics. The use of the computer as a tool of learning sounded fascinating to her. She admitted to herself that within most classrooms she had only seen the use of the computer as a reward or to do mindless practice.

### **Computer Capers—Learning the Program**

$\Theta_1$ : Diedre giggled excitedly as she and Sherry started the program. To her, this was like playing at a video arcade. She had only seen children use skill/drill math computer activities that were only a step above the worksheets she had done in grade school. Dr. Gee, the activity caricature, was explaining the connections between two-dimensional and three-dimensional figures. She was talking so fast that it was hard to follow. Diedre triggered the appropriate yes or no button, rather flippantly answering the questions that Dr. Gee asked. The two women huddled together trying to make sense of the program as well as trying to answer the questions on the activity sheet. It concerned Diedre that Sherry didn't seem any more competent than she was in geometry. She realized that she might have to shoulder more of her load on this assignment. The tasks required the two of them to concentrate, read, comprehend, and do what was asked. The two women capriciously explored the software, which later caused them to misunderstand aspects. For example, the women skipped over exploring some indicated items, as they did not want to risk answering an aspect incorrectly. The professor

approached on occasion, using prompting questions to help them focus on the task at hand. Clearly, this activity was challenging Diedre's ability to follow directions and to learn at the same time. She wished the professor would stand nearby and individually guide them on this journey.

Particularly puzzling was the new vocabulary needed for understanding. Dr. Gee had given the instructions to create the designated components of the task so fast. The women learned the meaning of the word net by listening to the conversations of others at nearby computers. Each woman questioned the meaning of the word face, and sought help from the facilitator. By the time they manipulated the cube's net to place the various required items on the faces, Diedre had learned to rotate the accompanying three-dimensional figure to see the other faces. Yet, Task 2--Prism Priming, seemed more puzzling. The two women had to synthesize their learning differently. As indicated in several different sources, Diedre was troubled by this new learning method. She was good at memorizing components of written sections of books and to dutifully regurgitate these ideas on a future test. Yet, Diedre suspected that her understanding of the connection among aspects of geometry was weak.

$\Theta_2$ : Since Bobbie was uncertain as to how to use the CD-ROM, she allowed Melinda Moore, her selected partner, to take the lead. With Melinda as the principle typist, she believed that her contribution would be minimal. It was not that she didn't want to learn, but instead she felt more comfortable taking a secondary role, especially when she felt less than confident in both geometry and in using the computer. "That's cute," Bobbie commented as the Dr. Gee caricature appeared on the screen querying the two women about the links between the net and the three-dimensional solid. Initially, neither woman knew some of the figures, particularly the distinction between the pyramid and the prism. They simply guessed, chuckled nervously when they were wrong, and tried once more. After learning about the rotation buttons from the facilitator, they began investigating in more depth: "A pyramid has a point, but this one has two long lines. . . . a cube is equal on all sides. . . . Is a triangular prism the same as a pyramid? . . . I don't think there is something called a square pyramid. . . . But, look at its bottom (Bobbie repeated three times). . . . Could we have a round pyramid?"

Bobbie and her partner Melanie felt secure in their understandings of the software as they started the concept development activity called Prism Priming. The two women chatted excitedly as they noted that the definition of the prism consisted of "rectangles that are connected by a similar shape on the top and bottom." Interestingly, she now identifies a face as "the whole area of one side of a shape." To her, a shape is a three-dimensional figure. This indicates that a generic meaning still supersedes a technical meaning. Bobbie is just beginning to notice the differing attributes of two-dimensional and three-dimensional figures.

$\Theta_3$ : Vicki Stevens and her partner, Betty Paluchi, excitedly began the Mighty Math™ software by clicking on the caricature, Dr. Gee. They quickly became

engrossed in the examination of folding the net into a solid. Dr. Gee asked, “Does this net match this solid?” By clicking either the yes or no button, they could respond appropriately and learn immediately if they were correct. Look, it’s a “three-dimensional figure, all laid out . . . if you fold it up, it makes a solid,” exclaimed Vicki. Some figures were easy to determine—just count the parts or faces. Other three-dimensional figures were more difficult. They had learned to “turn it over to find out about this one,” or click on the hint button. Vicki blurted out, “See, we were right! Oh, I get it now!” The women explored the *level* button and acknowledged that they were indeed at the beginner’s level. Before they moved to the Exploring Lab where they designed their own decorated cube, they paused to help others around them. Clearly, Vicki and Betty felt confident about this innovative computer program. Additionally, Vicki recognized the power of learning in a different style. “We discovered things by ourselves instead of being told everything. And, as a result, more learning took place,” she speculated. This concept development activity gave her an understanding of the meaning of constructivism since she had experienced the power of this type of learning.

### Understandings of Geometry

$\Theta_1$ : Diedre admitted that she “had a negative experience with geometry in her school days, because it was always *so boring*.” She indicated that “I have never been spatially adept. I get turned-around easily in new cities and am not able to read maps very well.” Furthermore, she had difficulty identifying the various components of the three-dimensional figure, such as a face or edge, except when prompted to do so. Although she decided that she “probably would have liked it more if my teacher had made it more interesting,” she appreciated “the way this program gave us a three-dimensional visual of our geometric shapes.” One of the Tasks—Prism Priming—was above her level of understanding, as it required her to recognize the shapes of the various faces, draw these and record their number on a chart. Sherry was helpful at this point so the task could be completed. “I really liked the concept of the program . . . but I would imagine that young children would become very confused the first time they used the program.” Was she really talking about herself?

$\Theta_2$ : Bobbie and Melanie worked together well, complementing each other’s strengths. Both solicited the other’s opinion and choices of answers throughout the adventure. Neither pointed fingers at partner’s errors but explored the software program learning from each other and Dr. Gee. They were evenly matched partners in both temperament and math knowledge sharing useful dialogue that assisted each with geometric development. Bobbie recognized that a pyramid has a *point* and could have different bases. She kept insisting that her partner “look at its bottom” when naming the type of pyramid. She used an analogy to characterize her understanding of a net after looking at several examples. “A net is like a [sewing] pattern.” However, she used technical language to describe a net on the activity sheet. Initially, they had difficulty creating the decorated cube. But when they accidentally erased their creation,

they started over rapidly completing the project. Bobbie carefully drew the triangular pyramid required in “Creative Ideas” activity. She helped her partner, Melanie, revise her misconception that all pyramids had to have a triangular base. Now, Melanie was aware of square and hexagonal pyramids.

$\Theta_3$ : Vicki and Betty enjoyed their geometry adventure. Vicki admitted she did not agonize at all with this activity “because I was enjoying the new adventure rather than dreading geometry. This computer program disguised the very fact that it was all about geometry. I probably learned more about shapes in this allotted time than I ever did in my school years.” Later, Vicki wrote in her journal, “When we worked on the computer assignment, I noticed . . . we were actively involved, we engaged in problem solving, cooperative learning took place, and we learned to figure it out for ourselves. I was familiar with some of the terminology used—such as net, and two-dimensional and three-dimensional figures—because I had read about these geometric concepts in the text. The computer, however, gave me a much better understanding of what I had read. For example, after seeing a net on the computer and manipulating various three-dimensional objects, I had a much clearer image in my mind of what the text[book] was conveying.” When asked to make her own definition of a prism on the activity sheet, “I realized what constructivism is about. It helped the light bulb go off in my head. It was such a fantastic way for me to learn a definition. I designed it myself. . . . By constructing the definition myself, I am not likely to forget it. Besides it was much more fun than looking up a definition in a textbook and then trying to memorize it for a test.”

### **Linking Language to Misconceptions**

$\Theta_1$ : The language Diedre used when discussing three-dimensional geometry points to her van Hiele low level of understanding just as the van-Hieles predicted. She referred to a sphere as a three-dimensional circular object, like a ball. She continued to improperly use the terms net and face. At times she was unable to distinguish between two-dimensional and three-dimensional, using these terms interchangeably. Several weeks after the activity was completed, she was unable to differentiate between a prism and a pyramid, stating that a prism was a pyramid as well as a three-dimensional triangle. Diedre was unaware that words could have more than one meaning.

$\Theta_2$ : Initially, Bobbie lacked the sophistication of language to be considered higher than van Hiele Level 0 with regards to three-dimensional figures. However, she was beginning to look at the various attributes of the solids as indicated by her awareness that a pyramid could have different shaped bases. The Multiple Meaning Words document shows that Bobbie had a clear understanding that words could have multiple meanings. However, she still possesses some misconceptions. Although Dr. Gee used the word solid throughout the program, with many models that were transparent, Bobbie still believes that “a solid is a three-dimensional shape that is filled.”

$\Theta_3$ : As shown by the Multiple Meaning Words document, Vicki recognizes that words can be generic or technically connected to mathematics. Several weeks after the she explored the Dr. Gee program, Vicki defined a net as “a pattern that can be made by covering a three-dimensional object with paper and having no overlapping pieces.” Her two definitions—a solid as “a three-dimensional figure having length, width, and height” and articulating the same definition of a prism as stated on her activity sheet—provide the indication that she has stabilized her van Hiele level as level 1—analysis. She could be considered at the beginning stages of van Hiele, level 2, since she is beginning to develop her own definitions of the various three-dimensional figures with ease. She is starting to visualize the attributes of the solids, recognizes faces and the positioning of parallel planes, but needs to concentrate on understanding the significance of edges.

### Findings

The data collected reveal some changes in each of the teacher candidate’s conceptual understandings of geometrical terms with increased recognition of two- and three-dimensional forms in the real-world as well as acknowledgment of differing definitions in the mathematical and real-world contexts.

$\Theta_1$ : Diedre’s geometrical development hinged on her willingness to explore and learn in depth, more than just acknowledging her weaknesses. However, Diedre’s geometric development was hampered because she simply went through the motions of answering the activity sheet questions, rather than enthusiastically choosing to learn more geometry. Although the two partners dutifully answered many of the questions, they explored a minimal amount of geometry with the software program. Diedre failed to recognize that through her own exploration she could increase her understanding of geometry. She operated in a teacher-mode” only rather than being a learner herself. Her attitude and view that the mathematics methods course is just one more hurdle to overcome on her way to becoming a teacher prevented her from maximizing her learning. Her non-awareness of multiple meaning words indicates that she compartmentalizes content subjects.

$\Theta_2$ : Initially, Bobbie was anxious about her understanding of geometry, but attained knowledge during the experience with the combination of perseverance and shared communication about understandings with Melanie. Additionally, she was a willing participant in seeking knowledge from this program. As the activity continued, she relaxed, enjoyed the adventure, and had no pretense of excellence. She was interested in learning more herself. After she felt comfortable with the program itself and turned the solid figures to inspect all faces, she participated in the concept development activity. Bobbie experienced some progress in understanding the differences between two- and three-dimensional figures. Now, she recognizes that nets are like patterns that create the three-dimensional solids. Additionally, she is distinguishing the shapes of the faces and how they make the sides of the figures. Although she

possesses some misconceptions herself, she noticed other misconceptions. She gently guided her friend to look at the bottom of a pyramid to distinguish its type. Evidence from the Multiple Meaning Words document shows that she was not hampered by the generic meaning of words used, but transcended this problem to learn more about geometrical figures. Still, she needs more experience in visually recognizing all three-dimensional shapes before she can be classified at another van Hiele level.

$\Theta_3$ : Although Vicki's understanding of geometry was initially more advanced than some of her peers, she faced this geometry session with apprehension. However, Betty's cheerful attitude helped as they began the program. Vicki's geometrical development advanced as she recognized that she didn't have to memorize the various definitions, but simply answer the questions asked, fill out the table, and connect the ideas together. She seemed to absorb the attitude of her peer, relaxed, and began to learn differently. She strengthened her foundation of geometry by recognizing the various attributes of the solids and how these are connected to the two-dimensional nets. This experience could have resulted in restricted improvement. Three situations prevented this: Vicki's positive attitude and interest toward wanting to learn more geometry, her willingness to tackle the previous procedural understandings by using the constructivist paradigm, and her absorption of the bubbly nature of her partner. She stated "I have learned that, when teaching students, technology can be used for much more than just word-processing and games."

### Conclusions

The three individuals had varying degrees of success. More importantly, this success seemed to be contingent on their attitudes toward learning more than their acknowledgment of their limited understandings. The individual who did not view herself as a learner was hampered throughout the experience. The two other participants, who were committed to learn in this constructivist manner, explored, conjectured—sometimes inaccurately, tried varying ideas, assessed their understanding by questioning and seeking peer advice, and generalized their suppositions. From these interactions these women increased their geometrical understandings of the links between two- and three-dimensional figures.

# **GROWTH AND DEVELOPMENT OF PRE-SERVICE ELEMENTARY TEACHERS' MATHEMATICAL KNOWLEDGE**

Mercedes A. McGowen  
Harper College  
mmcgowen@harper.cc.il.us

Gary E. Davis  
Washington State University

We detail the mathematical growth of a pre-service elementary teacher of the period of a semester. This student had an unusual combination of very poor basic computational skills and a capacity for higher level problem solving involving algebraic notation. We discuss the extent to which one or two semesters of mathematics content, however well-structured, is sufficient to develop deep understanding, much less pedagogical content knowledge, particularly when growth of mathematical reasoning and understanding are coupled with incorrect or inappropriate algorithms which have become automated over several years of use. We provide evidence that this student acquired new insights and understandings about mathematics and experienced changes in her attitudes and beliefs. However, we do not know whether the changes in attitudes and beliefs are short- or long-term nor whether what she learned is truly "owned" by her.

## **Introduction**

We are concerned, in this study, with the development of deep understanding of mathematics by pre-service elementary teachers. Those who teach mathematics content courses for pre-service elementary teachers are aware that, as they begin the mathematics content course, pre-service teachers' attitudes to mathematics are generally instrumental, focused on formulas and correct answers. We discuss and analyze what constitutes evidence of the development of deep understanding of mathematics by focusing on a young woman enrolled in a mathematics content course for pre-service teachers at a community college. This case study was carried out in a mathematics classroom and has important implications for linking research and practice. The issues raised in this study focus on what is theoretically desirable in a content course for pre-service teachers versus what might be practically attainable in one or two semesters. Effecting change in classroom practice based on research is not always straight-forward (McGowen & Vrooman, 1998). Yet research that provides evidence for what student growth in understanding and competence is attainable, and what the limits and applicability of those attainments are, is vital if mathematics content courses are to impact pre-service teachers deeply.

Many authors have addressed the question of growth of knowledge and growth of understanding in mathematics (for example, Ball & Bass, 2000; Clarke, Helme & Kessel, 1996; Davis & McGowen, 2001; Hiebert & Carpenter, 1992; Ma, 1999; McGowen, & Davis, 2001; Mewborn, 1999; Pirie & Kieren, 1994; Simon & Tzur, 1999; and Tall, 1995). The issues discussed in the literature acknowledge the importance and desirability of the growth of conceptual understanding and technical com-

petence. What is largely not addressed, however, is the extent and degree to which desired growth can be supported and encouraged in one or two semesters, and to what extent such a limited exposure to mathematics content for pre-service elementary teachers can impinge on decades of relatively negative experiences.

From a more quantitative angle, Hake (1998) and McGowen & Davis (2001) have utilized a measure of relative increase, pre-test to post-test, for whole classes and for individual students. This statistic—*gain factor*—is calculated as the ratio  $gain = (post-test\% - pre-test\%)/(100\% - pre-test\%)$ . Indications are that this statistic is related to student growth in a more cognitive sense (Hake, 1998; McGowen & Davis, 2001).

The main purpose of this study is not simply to re-iterate that pre-service teachers generally consider mathematics to consist of formulas and correct answers. It is also about how a particular person—Holly—develops considerably deeper understanding of mathematics over a semester, and how Holly's knowledge of mathematics may yet be insufficient for her to teach elementary mathematics effectively.

### Methods

The principal question of this study—"how does a pre-service teacher develop a deeper understanding of mathematics over a semester?"—is not easy to answer, and we need to indicate how our modes of inquiry will do that, and how our theoretical framework supports our question. At Harper College, prospective elementary teachers are required to pass a pencil-and-paper competency exam of basic arithmetic computations with a grade of 80% as a condition of successful completion of the first mathematics content course of a two course sequence. Students take this exam during the first week of the semester. They have two additional opportunities to take and pass the exam during the semester. Written work in the form of in-class tests, out of class assignments, and student reflections was also collected from students. Holly's written work was examined and analyzed in detail. Holly's work was analyzed in detail because of extraordinary incongruities in poor basic computational skills and outstanding higher order thinking skills. The individual gain factors were calculated for all students and Holly's gain factor located in the distribution for the class as a whole. Holly was also interviewed in relation to both her in-class and out of class written work.

### Results

On her initial attempt the first week of class, Holly correctly answered six of thirty questions (20%). Her answer to the first of the following two problems is shown in Figure 1. She did not attempt the second.

Only nine of the forty-six students who took the competency exam the first week of the Fall 2001 semester gave a correct response to problem (a). Thirty-two students—including Holly—gave incorrect responses to this question. Five students made no attempt to answer the question. Fourteen different incorrect responses were given for this problem, including Holly's answer of 266. Fifteen different incorrect responses were given for the second problem.

(a)  $3\frac{1}{2} \times 2\frac{8}{15}$       (b)  $1\frac{3}{4} \div \frac{1}{2}$

**Questions 6–11: Perform the indicated operation. Write your answer in lowest terms.**

Questions 6-11: Perform the indicated operation. Write your answer in lowest terms.

*Figure 1.* Holly's response to question on initial competency exam (Week 1).

On her second attempt eight weeks later Holly, like many others in the course, more than doubled her initial score to 50%. For Holly and the other 28 of 46 students who scored less than 30% initially, doubling the initial score on the second attempt midway through the semester indicates significant improvement but does not come close to satisfying the department's required passing score of 80%. The work on her 2nd attempt of the competency exam Question 6 (multiplication of two mixed numbers) is difficult to explain (Figure 2). Her work for Question 17 does not justify the answer and we are left wondering how it was actually determined. Though her work on Questions 27 and 28 is procedural and not as efficient as one might hope, she has

6.  $5\frac{1}{2} \times 2\frac{2}{5} = 1\frac{1}{2}$      $2\frac{2}{5} + 2\frac{2}{5} = \left(\frac{1}{2}\right)$     6.  $\frac{1}{2}$

17.  $\frac{1.5}{2.5} \times \frac{4.2}{5.2} + \frac{2}{3} + \frac{5}{9}$  - 17.  $\frac{8}{5}$

$$\frac{5}{10} \times \frac{8}{10} = \frac{40}{100} \div \frac{4}{10} = \frac{20}{50} + \frac{25}{35} = \frac{6}{15} + \frac{10}{15} = \frac{16}{15} \div \frac{5}{9} = \frac{8}{5}$$

28. Amy had 34 problems correct on a math test. Her grade was 85%. How many questions were on the test?

28. 40

$$\frac{34}{x} \times \frac{85}{100} \quad \frac{85x}{85} = \frac{3400}{85} = 40$$

29. Bruce earns a commission of 12% on all of his sales. Last month his sales totaled \$6125. What was the amount of his commission?

29. 735

$$\begin{array}{r} 61 \overline{) 7350} \\ \underline{1250} \\ 61250 \\ \underline{61250} \\ 0 \end{array}$$

$$\frac{12}{100} = \frac{x}{6125} \quad \frac{100x}{100} = \frac{73500}{100} = 735$$

Figure 2. Responses from Holly's second attempt on the departmental competency exam (Week 9).

represented these two problems appropriately and has written correct answers to these questions which she had not even attempted eight weeks earlier.

In an interview after taking the competency exam for the second time, Holly mentioned that she had studied the textbook's explanation of the theorem of addition of fractions with unlike denominators and the definition of multiplication of fractions to figure out how to do problems like Question 17, above. Holly had been unable to attend any of several review sessions due to scheduling conflicts so she attempted to learn a procedure she knew she did not know on her own using her textbook as reference.

In her mathematical autobiography, written at the beginning of the 16 week course, Holly describes her previous experiences with mathematics as follows:

Out of all the subjects that I have had to endure over the course of my education, Math has always been the most difficult for me to understand....The basis of all my math problems stems from the fact that I never learned the basics in mathematics....If I am asked a simple question such as: What does six times seven equal? I literally have to stop and think about it for a minute before I can come up with an answer.

Holly's responses to questions on an exam taken during the 12th week of the semester provide a startling contrast to her work on the initial basic skills exam and her midterm second attempt on this exam.

### Question 5:

Consider the set of numbers  $A = \{5, 6, 7, 8\}$  with a made-up operation called  $*$ . The rules for  $*$  are shown in the table below.

a) Is  $*$  commutative for set  $A$ ? Justify your response.

Student response:

Yes.  $*$  is commutative.

$5 * 5 = 8$     $6 * 5 = 7$     $7 * 5 = 6$     $8 * 5 = 5$   
 $5 * 6 = 7$     $6 * 6 = 6$     $7 * 6 = 5$     $8 * 6 = 8$   
 $5 * 7 = 6$     $6 * 7 = 5$     $7 * 7 = 8$     $8 * 7 = 7$   
 $5 * 8 = 5$     $6 * 8 = 8$     $7 * 8 = 7$     $8 * 8 = 6$   
 $5 * 6$  and  $6 * 5$  both have the same result of 7.  
 $7 * 5$  and  $5 * 7$  both have the same result of 6.  
 $5 * 8$  and  $8 * 5$  both have the same result of 5.  
 $6 * 7$  and  $7 * 6$  both have the same result of 5.  
 $6 * 8$  and  $8 * 6$  both have the same result of 8.  
 $8 * 7$  and  $7 * 8$  both have the same result of 7.

Therefore, the set  $A$  is commutative since this is true for all.

| $*$ | 5 | 6 | 7 | 8 |
|-----|---|---|---|---|
| 5   | 8 | 7 | 6 | 5 |
| 6   | 7 | 6 | 5 | 8 |
| 7   | 6 | 5 | 8 | 7 |
| 8   | 5 | 8 | 7 | 6 |

Figure 3. Operation table for question 5.

Recall that the gain factor for an individual student is the ratio  $(\text{post-test}\% - \text{pre-test}\%)/(100\% - \text{pre-test}\%)$ . Classes with average high gain factor (great than 0.5) correspond generally to reform type classes rather than more traditional chalk and talk type or drill type classes (Hake, 1998). Further, individual student growth in understanding of mathematics, as well as basic skills improvement, seems to be connected with higher individual gain factors (McGowen & Davis, 2001). Holly's individual gain factor was the 5<sup>th</sup> highest in a class of 33 students, and was a striking 0.85 compared with a class average of 0.58. From this perspective alone we should be alerted to possible significant cognitive growth in Holly's understanding of mathematics.

Holly's final grade (87%) was the sixth highest of the thirty-three students who took the final exam. Her final self-evaluation submitted with her portfolio in the sixteenth week provides confirmation of the growth of her mathematical understanding, and documents her changed attitudes and beliefs about mathematics and what it means to learn mathematics:

Reflecting on ... mathematics in August versus today now almost sixteen weeks later there is a significant difference on the way that I personally approach a math problem. In August I would: do the computation, focus of my attention being on the numbers within the problem, and usually not considering the content of the problem at hand. Once I received what I thought was the correct answer I would move on to the next problem and start the whole process over again. Now in December I focus my attention on the entire problem not just the numbers within it, I now look for alternative strategies and select the most appropriate and consider the context of the problem. Once I get a result I go through a series of reality checks: is this answer reasonable? Does this answer make sense in the context of the problem? Then I interpret my result by reflecting upon it and consider are there any other answers, strategies, possible explanations for the problem? When this process is complete only then move and I then on to the next problem to repeat the steps I just mentioned.

Holly shows evidence of higher order thinking and algebraic skills, which is particularly puzzling in light of her inability to carry out basic arithmetic computations. Evidence of her ability to think a problem through and reflect on her answer conceptually comes from her work on prime number values of a polynomial. Holly was interviewed after the Second Unit Exam had been submitted and asked to explain how the answer to the question below was determined. She said that both she and her partner had experienced an "AHHHH" moment. When asked to explain exactly what they had noticed that produced that AHHHH moment, Holly pulled out a copy of the spreadsheet she had created for testing various values of  $n$  in the equation and provided the following explanation:

- Proof and Justification was another method that was learned and relearned over the semester. In a mathematical problem there lays a claim setting restrictions on the problem's possible solutions and which must abide by these restrictions to be

labeled as a correct solution to the problem. Example six on the group exam gives such an example of claims and their relation to the process of Proof and Justification: *Does the expression  $n^2 - n + 41$  give only prime numbers? Explain your reasoning and justify your answer.*

- No, this formula does not always generate a prime number. If  $n = 41$ , the square root of the sum is 41.  $41^2 - 41 + 41 = 1681$  and  $1681 = 41^2$ .
- Our first approach to this problem was actually computing the expression and plugging in numbers up to 108 for  $n$  to determine if the result was a prime number. Next we looked at the actual number 41 more closely and tried other prime numbers in its place in the expression above to see if it would also generate prime numbers.
- This did not occur when we replaced 41 with any other prime number, therefore we knew that there was something special about the number 41 in this particular expression. Having this information on the number 41 created an AHHHHH moment in our minds and we decided to plug in 41 for  $n$  to see if the expression worked. This proved false and we found an example that proved that this expression was not true for all.
- In this problem the claim that existed was the number 41 giving only prime numbers, in other words is this prime number true for all numbers that you plug in the expression. To disprove a claim that there exists only prime numbers give one counter example, and now the claim true for all is proved false and is justified as well."

Holly's ability to reason mathematically by week 12 of the semester—to appropriately and effectively argue using a proof by exhaustion, to make and test conjectures, to recognize and represent relationships symbolically, and to clearly articulate what was done, both verbally and in writing—to make sense of the mathematics—provides a startling contrast to her earlier work on the departmental competency exam. Further evidence for this is provided by her responses to Question 11 on the same exam (Figure 4):

11. Find the smallest counting number that has the following properties: When it is divided by 2, the result is a perfect square number, and when it is divided by 3, the result is a perfect cube. Document all efforts and justify your conclusion.

*Handwritten notes:*  
 Maybe Divisible by 6, therefore "a" and "b" must be multiples of 6.  
 Since  $a^3 \times 3 = n$  will have the smaller multiple of 6, we started by using 6.  
 $6 \times 3 = 216 \times 3 = 648$   
 Then divided 648 by 2 -  $648 \div 2 = 324$ , took the square root = 18.  
 Page 4 of 4

Figure 4. Question 11: Unit II Exam (week 12).

Student response:

... even [written by the phrase *divided by 2*] and  $n = b^2 \times 2$ ;  $n = a^3 \times 3$ .

[The number] must be divisible by 6. Therefore “a” and “b” must be multiples of 6.

Since  $a^3 \times 3 = n$  will have the smaller multiples of 6, we started by using 6.

$$6^3 \times 3 = 216 \times 3 = 648$$

Then divided 648 by 2  $648/2 = 324$ , took the square root = 18.

Holly’s work on the open response final exam provides evidence of her growing ability to think flexibly and of her improved competence with fractions acquired during the sixteen weeks (See Figure 5).

(b)  $7\frac{3}{8} - 3\frac{1}{2}$

$7\frac{3}{8} = 6\frac{11}{8} = 6\frac{11}{8}$   
 $- 3\frac{4}{8} = 3\frac{4}{8} = 3\frac{4}{8}$   
 $\underline{\hspace{1cm}}$   
 $3\frac{7}{8}$

$7\frac{3}{8} = 7\frac{3}{8}$   
 $- 3\frac{1}{2} = 3\frac{4}{8} + \frac{4}{8} + 3 + \frac{3}{8} = 3\frac{7}{8}$

$7\frac{3}{8} = 7\frac{3}{8} + \frac{4}{8} = 7\frac{7}{8}$   
 $- 3\frac{4}{8} = 3\frac{4}{8} + \frac{4}{8} = 4$   
 $\underline{\hspace{1cm}}$   
 $3\frac{7}{8}$

Figure 5. Holly’s work on fraction problems in the final examination.

The week before the final exam, Holly still had not passed the competency exam with a grade of 80%—she had a 60%. Yet, a week later, on the final exam, she was able to not only do computations correctly with similar fraction problems, but demonstrated her ability to do the calculations in a variety of ways. She was given an *Incomplete* as her course grade and allowed to enroll in the subsequent course subject to passing the departmental final within six weeks of the next semester start-up. She did so and passed the competency exam with a score of 83%.

### Analysis

How does our data illuminate the issue of the growth of deeper understanding of mathematics by pre-service elementary teachers? Being able to use various algorithms correctly and selecting an efficient or elegant method of solution are often considered indicators of growth. For us, indicators of growth in deeper understanding of mathematics means that students are thinking more flexibly and systematically, able to articulate what was done, justifying why a method was used, generalizing their results, recognizing and building on connections between problems in different contexts and between various mathematics topics, and recognizing the role of definitions and proofs. Holly’s work on the competency exam contrasted with her classwork

and exams during the semester challenges us to re-examine our traditional notions of evaluation and assessment. What constitutes evidence of learning? What do our traditional methods of assessment tell us?

How much of what she has learned will Holly retain and use over time? On the one hand, Holly, like many of her colleagues, has struggled to re-learn computational algorithms which had become deeply-fixed habits of automatic, incorrect responses learned previously, and she experiences debilitating mathematics and test anxiety under stressful conditions like the high-stakes competency exam. Despite these obstacles, Holly, and many others, demonstrate the ability to develop more flexible ways of thinking as they investigate problems and reflect on their work during the semester. They make sense of the mathematics they are learning and build connections—having realized that in order to make connections, they “have to have something to connect.” Their language grows more precise, what they focus attention on initially changes, and mathematical marks become truly symbolic. The change in attitudes and beliefs, coupled with their growth in understanding and improved competency is evidence of the changes that have taken place.

The inability of preservice teachers like Holly to demonstrate competency of basic arithmetic computations at the beginning of the semester has not proven to be an accurate predictor of their ability to think mathematically—to represent problem situations, make connections, justify their work, use mathematical arguments, or to think flexibly and systematically. Since Fall 1996, only 4 of 206 pre-service elementary teachers who attempted the course passed the departmental competency exam on their initial attempt with a grade of 80% or higher of those who enrolled in the first content course. One hundred fifty-five of the 206 students completed the course and took the final exam—a 75% completion rate. Of those who completed the course, 96% (149 of 155) were successful, i.e., passed the course with a grade of C or better and passed the departmental competency exam with a score of 80% or better on either their second or third attempt.

### Discussion

What are reasonable expectations of students who enroll in a mathematics content course with deeply held beliefs about mathematics and what it means to learn mathematics that reflect a strictly utilitarian perspective of mathematics that often limits their mathematical vision? The complexity of the task in determining answers to our questions is illustrated by an examination of the work and comments of one elementary pre-service student. If, as seems clear to us, deeper understanding develops over time, should we focus our efforts on providing students with pedagogically sound experiences of what it means to learn mathematics and then direct subsequent efforts to building on and transforming that foundation knowledge of mathematics into pedagogically useful content knowledge? Can students like Holly think about how to use their mathematical knowledge in the classroom when their mathematical foundation

lacks both conceptual understanding and skill competency in the mathematics that is the basis for what they will be teaching? Holly's initiative in opening and following the textbook to carry out fraction calculations is to be applauded—she wants to be a teacher and is highly motivated. However, her interpretation of the text is an example of “a little learning is a dangerous thing.” What is symbolic and meaningful for those with the mathematical knowledge to interpret the symbols and an understanding of the implicit assumptions about the product in the denominator is, in the given context, simply a rule to follow in order to get the answer for students like Holly who attempt to interpret the marks with limited mathematical understanding.

What constitutes evidence of deep understanding? Is it being able to recognize which algorithm a student is using? Is it being able to calculate an answer using various algorithms and being able to choose between known alternative methods and selecting the most efficient/elegant method of solution? Is it being able to articulate what was done, why the particular method used is valid? Is it demonstrating the ability to recognize connections given isomorphic problems in different contexts? Is profound understanding attainable in a sixteen week semester? Over two semesters? By the time the pre-service teacher graduates? If a deep understanding of the mathematics that pre-service teachers need to know takes years to develop, then we need to consider what is possible over time and what is reasonable to expect of pre-service teachers.

The pre-service elementary students who enroll in mathematics content courses at many institutions — particularly at two-year colleges and other institutions with open enrolment policies—are in need of a mathematics content foundation to think with before they are able to think about how to use their mathematical knowledge in the classroom. If our goal is the development of deep understanding of mathematics by those who will be our future teachers, then the various constituencies involved in teacher preparation need to align their instructional goals and practices across institutions so that the development of profound understanding can develop over time. There is, in our view, no doubt that this is a developmental issue, and one that is compounded because it is about development in mathematics by adults for a professional purpose. It seems to us that there are profoundly important educational issues at stake here, and that much focused and penetrating research is required to answer a number of fundamental questions. We believe the results presented here are of significance to those interested in the growth of mathematical knowledge of pre-service elementary teachers. Above all else, we feel, this is a question of considerable interest for the mathematics education community.

# **TEACHING MATHEMATICS WITH TECHNOLOGY: THE ROLE OF HIGHER EDUCATION IN LINKING THEORY WITH PRACTICE**

Regina M. Mistretta  
St. John's University  
mistretr@stjohns.edu

Today's technology standards (ISTE, 2000) challenge teacher education programs across the nation to address the need to produce computer literate teachers for the 21<sup>st</sup> century who are confident in their ability to choose and incorporate instructional technology into their classroom teaching. The purpose of this paper is to present a description and an analysis of the affects of training sessions on pre-service teachers' ability to appropriately select mathematics instructional technology for use in the everyday classroom. A group of 51 pre-service teachers participated in training sessions where they used a critical eye to evaluate the features of various PreK-12 mathematics software and websites for instructional purposes. Quantitative analysis methods were used to assess the pre-service teachers' prior mathematics learning environments and specific experiences using technology; while qualitative analysis methods were used to search for patterns of affect on the pre-service teachers' beliefs and confidence in using mathematics software and websites to create a technology-based learning environment.

Today's technology standards (ISTE, 2000) challenge teacher education programs across the nation to address the need to produce computer literate teachers for the 21<sup>st</sup> century who are not just knowledgeable of the internet, word processing programs, spreadsheets, and presentation software, but are also confident in their ability to incorporate instructional software and websites into classroom teaching. Levine and Donitsa (1998) state that computer literacy involves not only the knowledge, understanding, and value of technology, but also a positive attitude in one's ability to apply the theory related concepts to classroom instruction. Unfortunately, Lederman and Neiss (2000) report that technology courses that are part of teacher preparation programs often place emphasis on pre-service teachers learning about technology rather than on learning how to teach their subjects with technology.

Significant changes in teaching and learning have emerged due to the integration of technology and curriculum. Weglinsky (1998) reports data from the 1996 National Assessment of Educational Progress in Mathematics that find both teachers' professional development in technology and the use of computers to teach mathematical concepts and higher order thinking skills to be positively related to academic achievement in mathematics. Despite these results and the growing access to technology, Kent (2001) reports the U.S. Department of Education as calculating only 20% of 2.5 million public school teachers feeling comfortable using technology in the classroom. Of the full-time faculty, 99% have access to computers and the Internet somewhere in their schools. Of that group, across all grade levels, only 39% reported using

computers or the internet “a lot” to create instructional materials; 34% used them for record-keeping; and less than 10% used them to access lesson plans, do research, or investigate best practices.

Neiss (2001) reports the National Council of Teachers of Mathematics as pinpointing technology as an essential component of the Pre K-12 mathematics learning environment due to its ability to influence the mathematics that is taught as well as enhance students’ learning. Kerrigan (2002) has found the capabilities of mathematics software and websites to include promoting higher-order thinking skills, developing and maintaining computational skills, introducing children to collecting and analyzing data, facilitating algebraic and geometric thinking, and showing the role of mathematics in an interdisciplinary setting. As one reflects on the powerful influence that mathematics instructional technology can have on teaching and learning, the role of higher education becomes evident.

Drier (2001) states that teacher educators are challenged with the task of preparing pre-service and in-service teachers to incorporate technology in ways that will develop a deep understanding of mathematics for themselves as well as for their students. Haughland (2000) states that how computers are used is more important than if computers are used. Selection of appropriate software and websites is key to the ultimate success of integrating instructional technologies into classroom teaching. Therefore, the need for teacher preparation programs to serve as catalysts for the implementation of technology into the mathematics classroom is vital.

The purpose of this paper is to present quantitative and qualitative research efforts that investigate the affects of mathematics software and website evaluation training sessions on pre-service teachers’ awareness of, confidence with, and appreciation for the use of technology in the teaching of mathematics. A group of 51 pre-service teachers enrolled in a required sophomore year 15-week long technology course participated in training sessions where they learned how to use a critical eye to choose appropriate mathematics software and websites for use in everyday classroom teaching. Patterns of affect on the pre-service teachers’ beliefs and confidence in using software and websites to create a technology-based learning environment in the mathematics classroom are reported in this paper. Findings are shared in order to provide teacher educators with information that may serve them when planning programs that will prepare educators to effectively integrate technology into classroom instruction.

Abilities, knowledge, and skills in teaching with technologies are emphasized in the preparation of teachers so they may make informed decisions about which technologies to use for teaching specific topics of the mathematics curriculum. The primary goal of the training sessions described in this paper was to engage pre-service teachers in evaluating mathematics software and websites in order to prepare them to select and implement appropriate instructional technology into the mathematics learning environment. Projected outcomes included enhanced awareness of and appreciation for the capabilities of technology in the learning process as well as heightened levels of

confidence in selecting and implementing software and websites into the teaching of mathematics. This conceptual framework stems from the constructivist approach that proposes the development of insights and skills to support future teachers in making informed and rational decisions when confronted with instructional choices concerning technology and the mathematics classroom.

### **Initial Assessment**

Halpin (1999) states that teachers often teach as they were taught. Therefore, prior to the training sessions, an investigation into the pre-service teachers' past mathematics learning environments as well as their knowledge and specific experiences concerning technology was conducted in order to gather information about prior learning. A survey was administered that sought information concerning the mathematics pedagogy and tools that the pre-service teachers' experienced as students at the Pre K-5, 6-8, and 9-12 grade levels. The first part of the survey required the pre-service teachers to indicate the presence or absence of specific features in their prior learning of mathematics. These features were explained and included the following: teacher-centered instruction, student-centered instruction, convergent questions, divergent questions, conceptual development, computational skill building, cooperative learning, memorization and drill exercises, journal writing, applications, interdisciplinary connections, problem solving strategies, manipulatives, games, texts, and worksheets. The second part of the survey focused on the pre-service teachers' prior uses of instructional technology as well as their self-confidence to select appropriate software and websites for use in the mathematics classroom. They were asked to supply the specific software titles and websites they had previously used at school, home, and/or work, along with an explanation concerning their reason for using the specified software and websites. They were also asked to indicate their self-confidence in evaluating the quality of instructional software and websites, and to comment on how they would select appropriate software and websites for use in the mathematics classroom. After the survey was administered, interviews with the pre-service teachers were conducted where they could speak candidly about their survey responses. These interviews provided the opportunity to gain a deeper understanding of the pre-service teachers' written responses.

Data collected from the surveys and interviews indicated that the majority of pre-service teachers' mathematics learning environments focused on computational skills rather than on the development of conceptual understandings, problem solving strategies, and higher order thinking skills. Memorization and drill of basic facts, definitions, and formulas was common at all levels while activities such as journal writing and mathematical games were practically non-existent. Their responses revealed that the most common experienced teaching technique at the Pre K-5, 6-8, and 9-12 levels was teacher-centered instruction where lecture from the teacher was basically the sole means of communication. Discourse amongst students was rare. Their conception of

cooperative learning was where a group of students “sat together” to work on their examples and ask each other for help when needed, rather than a group of students working as a team, each dependent on the other, to accomplish a common goal. Most of the pre-service teachers were used to convergent questions where one correct answer and method of solution were present. Opportunities for discussion concerning multiple methods of solution and multiple correct solutions/representations made possible by the use of appropriate divergent questioning and problem solving situations was not a common memory for many of the pre-service teachers. The use of manipulatives declined rapidly as the grade levels increased. Common learning tools were textbooks and worksheets. Applying mathematical concepts to the real world and/or other discipline areas was a rare event for these pre-service teachers. Many commented with statements such as “I couldn’t see how I would ever use some of the math I learned in school,” and “Many times I found myself frustrated because the math I was learning had nothing to do with anything else I was learning.”

The most familiar computer application reported by the pre-service teachers was word processing. Most had used Word Perfect for typing research papers. A small number had created spreadsheets with Excel and designed presentations with PowerPoint. A vast majority of the pre-service teachers had used the internet, but only for the purpose of e-mail. Few had conducted research on the internet. Using technology for instructional purposes was not widespread. Of the few pre-service teachers who had used software for instructional purposes in school, only one did so on a regular basis in science class. The others reported sporadic use of software that didn’t relate to classroom topics. The software they used at home was geared towards test preparation for standardized tests. Those who used software at work did so in an after-school program where children, ages 4-6 used reading and math readiness programs. All of the pre-service teachers felt insecure in their ability to evaluate mathematics software and websites. Their comments revealed that the majority would not know where to begin if asked to evaluate instructional software and websites for the mathematics classroom. Many thought that the mathematics software and websites were just games the students could play once the content was mastered.

### **Description of Training Sessions**

The training sessions were designed to prepare the pre-service teachers for entrance into their own classrooms not only aware of the capabilities of mathematics instructional technology, but also with the knowledge and confidence to appropriately select and integrate software and websites into their teaching of mathematics. The sessions began in a whole group instructional setting where two 1-hour class periods were spent discussing how to evaluate mathematics software and websites. The pre-service teachers were guided to use criteria and consider the following when viewing the software and websites: the mathematics standards covered, use of higher order thinking skills, ability to sustain interest, grade level, ease of use/free from technical

flaws, ability levels, reading level, use of demonstrations/models/visual aids, appropriate color/sound/graphics, conceptual development, skill building, problem solving strategies, applications, interdisciplinary connections, as well as accurate information and interactive features/feedback. The pre-service teachers were also instructed to look for the degree of access to background information, evidence of effectiveness, the presence of record-keeping, and complete documentation/site supporters. After the introductory discussion about the criteria one should use to evaluate software and websites, the pre-service teachers as a whole group were guided by the instructor to evaluate two pieces of mathematics software and two mathematics websites. During the guided discussion, each of the criteria was addressed for each of the viewed software and websites. The similarities and differences existing amongst the software and websites were discussed as well as their appropriate uses in the mathematics classroom. The dominating strengths of the viewed pieces of instructional technology were noted and used to begin a discussion concerning the value of distinguishing between those programs and websites best suited for whole group instruction and those suited for small group instruction. In addition, the software and websites most effective for purposes such as conceptual understanding, skill building, applications, and interdisciplinary connections were addressed. For example, the pre-service teachers reasoned how the software and websites that contained visual displays and multiple representations would be appropriate for developing mathematical concepts while those that engaged the students in real-life situations such as owning a business and investigating architectural designs were best suited for problem solving, applications, and interdisciplinary connections. The pre-service teachers considered the interactive feedback features where students were guided to arrive at correct answers as well as multiple methods of solution when possible. They also looked for record-keeping aspects of the software and websites as a form of student assessment. Throughout the discussion the feedback from the pre-service teachers was recorded and used as a means to summarize their findings.

The pre-service teachers were then paired as a team and asked to evaluate in the same manner as before two additional pieces of software and two additional websites during the next two 1-hour class sessions. Each pair was given different pieces of software and websites and was instructed to take notes on their findings. Their notes were later used to prepare for class presentations concerning the software and websites that they evaluated. Throughout this assignment, the students were observed to take note of their level of engagement as well as their reactions to the evaluation procedure. Visits were made to each of the pairs to discuss the instructional purpose of the software and websites they were evaluating. When evaluations by all teams were completed, the next two 1-hour class sessions were spent discussing their evaluations. Each of the teams presented their findings to their peers based on the given evaluation criteria. They justified their evaluations by demonstrating specific features of the programs and websites that caused them to reach particular conclusions. Feedback

from their classmates was elicited. The discussions that followed each of the presentations gave the pre-service teachers an opportunity to voice opinions, share insights, and become actively involved in the decision making process involved in selecting instructional technology for the mathematics classroom.

The same student pairs were given the assignment of developing a technology-based lesson plan that incorporated either a piece of software or a website as their main technological teaching tool. They were also asked to incorporate an appropriate follow-up activity to the lesson that would incorporate a piece of instructional technology that was not used in the main portion of the lesson. For example, if a team developed a lesson about fractions using a piece of software, their follow-up activity used a website concerning fractions. The students were given time throughout the remainder of the semester to plan while guidance and feedback was given by both the instructor and fellow classmates. The teams made decisions concerning issues such as whole group versus small group instruction, alignment of software and websites with lesson objectives, and methods of assessment. The lessons were presented using PowerPoint, and selected software and websites were viewed. The rationale for choosing particular software and websites was discussed by the presenting pair. The presentations demonstrated their educated use of the given criteria as well as their collaborative efforts in the decision making process. As before, feedback from their classmates was shared. The discussions at this point in the training sessions portrayed the pre-service teachers not only as active participants in the evaluation process, but also as practitioners of technology-based mathematics lessons.

### **Conclusions and Recommendations**

Upon completion of the training sessions, the pre-service teachers were asked to reflect on their experiences evaluating mathematics software and websites and incorporating them into lessons. During interviews, each of the pre-service teachers was asked to comment on both the positive and negative aspects of the training sessions, their viewpoints concerning the value of integrating technology into the mathematics curriculum, and their level of self-confidence in selecting and incorporating instructional technology into classroom mathematics teaching. Collected data indicated that the vast majority of pre-service teachers viewed the sessions as a completely positive experience. Of those responding that the training sessions were not completely positive, the only negative aspect reported were technical difficulties that infrequently occurred when a program wouldn't run or a website wasn't responding. Their responses revealed that they appreciated having a structured set of criteria that they used consistently throughout the evaluation process. The pre-service teachers enjoyed working with a partner and sharing their findings with others. They indicated that the "support system" that the design of the sessions allowed for gave them the opportunity to brainstorm with another person and refine their ideas. The majority viewed the development of technology-based lessons as a hands-on experience that put theory

into practice. Many of the pre-service teachers made comments such as “It was helpful to have us all present our evaluations. This way we saw more than just what we were assigned,” and “By actually incorporating a piece of software and a website into my own lesson, I feel I did what I learned to do.”

Patterns in the pre-service teachers’ responses were noted and organized into three categories: heightened awareness of the capabilities of technology, stronger levels of confidence in selecting software and websites, and deeper appreciation for technological resources. The majority of the pre-service teachers responded that they were more aware of the uses of instructional technology in the mathematics classroom as a result of the training sessions. They specifically noted software and website capabilities such as: development of mathematics concepts, skill building, use of problem solving strategies, demonstration of mathematical applications, and provisions for interdisciplinary connections that they were not aware of prior to the training sessions. The pre-service teachers as a whole commented that they were more confident in the process of selecting software. They indicated feeling better about their ability to choose instructional technology that was appropriate for age, ability level, and mathematical topic. Quotes included “We didn’t just accept the first thing we saw,” “We selected tools that were relevant, motivational, and would really benefit kids,” and “We were able to pick it apart and see both the positives and the negatives.” The majority of the pre-service teachers viewed instructional technology as a tool that can enhance the mathematics learning environment and provide a much richer experience than they had as students. They reported feeling at ease knowing that they electronic technologies would support their efforts to create a mathematics classroom comprised of hands-on exploration, reflection, and problem solving.

Conclusions rendered from the findings of this study warrant not only recommending the inclusion of instructional technology evaluation skills into teacher preparation technology courses, but also that those learned skills be used in higher level methods courses to build awareness of resources and enhance teaching techniques in all disciplines. Teachers hold the key to the effective use of technology in the classroom. Promoting awareness of, appreciation for, and confidence in one’s ability to select and use instructional technology can help put theory into practice and increase the numbers of those who teach with technology and thus enhance classroom teaching and student achievement.

## **PRESERVICE TEACHERS UNDERTAKE DIVISION IN BASE FIVE: HOW INSCRIPTIONS SUPPORT THINKING AND COMMUNICATION**

|                          |                          |                          |

In this study, preservice elementary teachers, working in two groups, solve division problems using different number systems in base five: a place-value system and an additive system. In the first system, the students' algorithm displays symbolically the numerosities on which the formal steps are based. To divide using the second system, the students' quotient emerges as a missing factor, found by filling blanks in a multiplication algorithm that the students had developed first. Their construction takes advantage of special features of their number system, features that place value numbers do not share. To analyze the work considered here, we focus on the students' inscriptions, both as parts of thinking and as parts of an evolving discourse about methods and their grounding.

This paper is one of two that focus on the use of mathematical inscriptions.<sup>1</sup> Both papers give case studies of how groups of learners grapple with important concepts in surprising ways. In each case, despite large differences in age and setting, understanding what the learners write and draw supports key steps toward understanding how they learn.

In this report, we follow two student presentations about whole-number division, using contrasting number systems in base five. We have drawn these student presentations from extensive data gathered in an extended teaching experiment in the mathematics content sequence for elementary education undergraduates at our university. In this teaching experiment, now in its fifth year, we have worked with classes of about twenty-four students for two semesters at a time. Thinking ahead, not just to the later methods course but also toward our students' subsequent professional development, our experimental teaching focuses primarily on how our students work collectively to solve challenging, extended problem tasks and then present and justify proposed solutions. We have avoided lecturing. Instead we have emphasized selecting and proposing tasks we hoped would trigger the development of important mathematical concepts by the learners. We have been especially interested in how the need to build convincing explanations, arguments, and justifications might help to deepen student inquiry and discourse.

### **Background and Guiding Frameworks**

Research by the first two authors, begun in 1995, has centered on how mathematics learners construct, represent, explain, debate, reconsider, reconstruct, and justify

their mathematical ideas. In our work so far, the rich variety of representations that learners build (including graphs, diagrams, written symbols, gestures, or specific language use) in order to develop and convey ideas, results, and lines of reasoning has been especially striking. For us, a representation is a *presentation*,<sup>2</sup> perhaps to oneself, as part of an ongoing thought, or perhaps to others, as part of an emerging discourse (Speiser & Walter, 1997). Here we focus on *inscriptions*: things that people write and draw.

The approach we take to classroom research builds from the guiding principle that learners must adapt their current understanding when they encounter problems where their prior understanding proves inadequate. Hence we view the growth of understanding as a process of assimilation and accommodation. In particular, we design instruction, primarily by selecting, developing, and posing problem tasks that challenge students to revisit, reconsider, and perhaps to reconstruct prior ideas, techniques, knowledge, and understanding, in detail and at length. We see the building and discussion of inscriptions as essential to the building and communication of important mathematical concepts.

### **Rationale**

The need to build instruction based on learners' prior experience and current thinking hardly seems to need discussion. How to meet that need, however, has been the subject of considerable debate. For preservice elementary teachers, the need to gain strong understanding of the mathematics they will help children to learn presents, we think, two major challenges: our students' prior experience, often through instruction which has failed to meet their need to build important understandings through their own successful efforts, and the need to help our students make productive contact with successful work and thinking, not just by themselves or by their peers, but also by young learners.<sup>3</sup> In our teaching experiment, we and our students both take challenges head-on. Here we concentrate on how our students meet the first one: to build a new, more helpful, mathematical experience.

### **Data Sources and Task Design**

The student work reported here took place in October 2001, in two sections of our experimental mathematics course. Both sessions were videotaped by one camera that followed focus groups, filmed student presentations, and also panned around the room. The data we discuss are drawn from student presentations. We collected students' written work after each session. Further, at the end of the semester, students submitted journals and reflective essays, which we have also found useful. Key events from the videotapes were transcribed and checked by three people, in preparation for analysis. The task reported here was the number system task developed in 1995 and described in Speiser & Walter (2000). Before the data given here, each student group built a number system using the symbols O, A, B, C, and D, with two requirements: (1) the

given number system should be compatible with standard base 5 blocks, and (2) the given system should allow them both to count and do arithmetic. The student work reported here discusses long division in two different number systems: a place value system in base 5, and an additive system based on an extended set of blocks.

### Methods or Modes of Inquiry

The interpretation of inscriptions and their use will help us to track important changes in the work and thinking of the learners. Individuals might build them, for example, to present aspects of their own thinking to themselves. But, once an inscription has been made, groups of learners can then work with it, either socially or individually, in different ways. We will treat inscriptions, suitably interpreted, as parts of thoughts that can be readily inspected, both by learners and by us. As explicit objects of construction, argument, reflection, reconstruction, and perhaps debate, their analysis can help to anchor narratives about the learners who have worked with them. These narratives, in turn, may help to clarify, and possibly support, hypotheses about the learners' work and thinking. Hence, we will surround given inscriptions with transcript data, background information, and interpretations, through which ideas contributed by specific individuals can be seen as informing (or perhaps failing to inform) the discourse of a group.

### Data and Analysis

In our classroom, we had already used a set of base 10 blocks. In the statement of the new number-system task, however, we asked our students to imagine a set of base 5 blocks, indicated by line drawings on the task sheet. The base 5 blocks were designated as follows. The 1cm cube was called a *piggy*, by then a longstanding local usage, explained by Speiser and Walter (2000). The next three blocks, in ascending sizes ( $5 \times 1 \times 1 \text{cm}^3$ ,  $5 \times 5 \times 1 \text{cm}^3$ ,  $5 \times 5 \times 5 \text{cm}^3$ ) were respectively called *longs*, *flats* and *solids*. We now present and analyze two data segments, in which two different student groups explain division in their (very different) number systems.

The first inscription to be analyzed appears in Figure 1 below. Five students have built a place-value system in base 5, where the symbols O, A, B, C, and D represent the cardinal numbers zero through four, respectively. Thus, for example, CDD represents three flats, four longs, and four piggies, giving 99 if we convert to base 10. They have posed the problem CDD divided by D to illustrate their method of division. This is shown in Figure 1, at the right, as one student, Heather, writes as she explains:

So, we have D's into C's, and D's won't go into C's. So, we need to break the C's into the long position. So, that's a 1, that's [smiles, laughs] A [i.e., one] C. [Writes 5 tally marks below the first D in the dividend.] B long [Writes 5 more tally marks below the first 5.] And C, long. [Writes 5 more tally marks below the first 5, then draws three arrows from the C to the three groups of tally marks.]

Figure 1. Heather's inscription.

So this is how, this is converted, over...

So and we need D groups. So, here's a D group [Circles the four tally marks on the row just underneath the D.] Here's a D group, with that one, that's not in there [Circles the four leftmost tally marks on the 2<sup>nd</sup> row underneath the D.] Here's a D group [Circles the four leftmost tally marks on the 3<sup>rd</sup> row underneath the D.] Here's a D group [Circles the four leftmost tally marks on the 4<sup>th</sup> row underneath the D.] And we have C left over. [Marks each uncircled tally mark in that column with a dot, draws a line beneath the column, and writes C below the line.]

So we have D groups. [Writes D above the division bar.]

With C left over [Points to the C at the bottom.] and then the D drops down. [Writes the D next to the C and then writes the tally marks below D and then below the C.]

The C in CDD has been decomposed into three groups of five tally-marks, placed below the D in the next column. Groups of four (i.e., D) tallies have been circled, leaving a vertical column of "I"s, each marked by a dot. Once these D's have been accounted for, the three "I"s marked with dots give C below the horizontal line, and then D is brought down. This is quotative division: this method (Speiser, Walter, & Lewis, 2001) asks how many Ds can be taken out of CDD. The use of tallies seems to symbolize<sup>4</sup> more abstract objects, that the numbers denoted O through D can be inter-

preted as counting. In the transcript of the students' conversation, these abstract counters are identified, at different times in different ways, with particular base 5 blocks. The tally marks make clear that Heather, as spokesperson, as well as other members of her group, are counting with composite units (Olive & Steffe, in press; Steffe, 2001), much as children have been seen to do when working with fractions.

In a second data segment, a different group of students use an additive base 5 system, somewhat analogous to Roman numerals, to develop a completely different algorithm: to find the quotient as a missing factor. In their inscription, they successively fill blanks in a previously-developed algorithm for multiplication, where one factor and the product have been given, in order to determine the second factor. Their method depends on the additive nature of their number system, in which products emerge naturally as rectangular arrays (see Figure 2, right for an example).

This group's number system works as follows. The symbols A, B, C, D, and O are used to represent different sizes of blocks. The symbols A, B, C, and D represent, respectively, the piggy, the long, the flat, and the solid. This group invented a further *imaginary* block, equivalent to five solids placed end to end, which they denoted by the remaining symbol O. They called this final block a *big long*. Numbers are then represented additively (somewhat as in the Roman system), by juxtaposing symbols. Thus DDCBBAAA represents two solids, one flat, two longs, and three piggies. Adding and subtracting lead to quite straightforward algorithms. Multiplication, however, becomes very interesting.

To multiply, the group first built a table (Figure 2, left) to tabulate products of the basic blocks, which they called the *chart*. Then they found more complicated products by constructing rectangular arrays. For example, the product of CBBBAA by CBBA A led to the inscribed algorithm (Figure 2, right), a mosaic of rectangular arrays. The product, after combining the blocks indicated, is ODDCCAAAA.

Figure 2. Left: the products of the basic blocks. Right: the chart for CBBBAA times CBBA A.

To divide, two group members, Jana and Heather (a different Heather from the first example), reversed the multiplication process they had just demonstrated, dividing the product, ODDCCAAAA, by the factor CBBA. To do so, they created a blank multiplication diagram (which we will call the *workspace*), wrote the divisor CBBA down the left-hand side, and proceeded to determine the second factor step by step, by filling in the workspace one column at a time depending on successive entries for the second factor at the top margin of the workspace. To make this clearer, Figure 3 (left) shows one step of the process: beginning the second column of the workspace.

Figure 3. Left: the workspace, with Jana ready to fill in the second column. Right: the corresponding tree.

To the right, we see a further inscription (Figure 3, right), which we will call the *tree*: a diagram the students used to keep track of the given product (that is, the dividend, ODDCCAAAA), with entries crossed off successively as they were either moved into the workspace or replaced in the tree (indicated by vertical lines) by equivalent collections of smaller blocks. To summarize the process, the first O in the product was moved into the upper left corner of the workspace. By the chart, we have  $O = C \times C$ . Therefore, the first C of the divisor (CBBA) forces C into the first place in the quotient of the workspace. Then the first column of the workspace can be filled in by the products given in the chart, and finally the first O in ODDCCAAAA is crossed off in the tree, and then the further entries (just found) below O in the first column in the workspace.

In the following data segment, Heather and Jana discuss the first C in the workspace quotient, and then the entries in the first column of the product which appear below it.

Jana: Umm, to figure out what would go on top, you can see that over here an O and a C would be another C. So you can work that way with

our chart. So the C would go on top there.

Then, we see that a C times a B on the chart is a D ... D, C, C. So now we can cross off D, D, C, C and we have left, what we have left is O, A, A, A, A.

Umm, we have an O left [referring to the tree], but if we put the O there [in the workspace, where the D appears in Figure 3, left] all we would have left after that would be 4 A's and we couldn't fill in the rest of the column, so we are going to have to go one lower than that to a D. [Writes a D to the right of the O inside the product in the workspace.]

And so in order to do that, we break this O [in the tree] down into 5 D's. [Heather crosses off the first O, 2 D's, and 2 C's in the tree. Then, she writes 5 D's below the 2nd O in the tree. Meanwhile, Jana, at the workspace, turns toward Heather.]

Heather: This many D's.

Jana: This many D's. [Displays 5 fingers.]

We read this data segment as a presentation, for the other students in the class, of how the steps described here were discovered. In particular the last two lines of dialogue look (at least to us) like a spot check for the number of D's that give an O, which, by definition, will represent the number of flats that constitute a solid. At this point *three* inscriptions are in play: the workspace, the chart and the tree. The latter two, in a sense, are used as tools for building up the workspace, where the sought-for quotient is to be assembled. Each inscription, in a different way, presents important parts of their authors' thinking to themselves, as they made decisions about how, step-by-step, they should proceed. Here, in our view, they serve a somewhat different function, to help the speakers narrate their sequence of decisions to the class, perhaps anticipating questions from the floor.

Very soon, two students, from other groups, in different places in the room, indeed pose questions. These questions will trigger *shifts* in how the three inscriptions (perhaps especially the workspace) work within the student discourse.

Erin: [From across the room.] So, the answer is just going to be what's on top of the line, right?

Jana: Right.

Erin: Okay. [Jana looks back at Heather, who is writing on the board.] ...

Erin: And what's the stuff below again? It's like your ...

Jana: This in here? [In the workspace, Jana points to the area inside the lines.]

Erin: Yeah.

Jana: That's our ... what we're dividing, [Points to the dividend problem statement written at the top of the overhead.] we're breaking it down until, until it fills ... the square perfectly.

Jana: Because, yeah, does that make sense?

Andrea: [From one side.] How did you get the first O in the first place? I don't remember that.

Jana: We just took our, largest num..., our largest letter which was an O and stuck it in there. [Points to the first O in the dividend in the problem statement.]

Andrea: Is that what you always do? Just take the largest one?

Jana: Right, and if, and if, if we break everything down and realize that ... um, we don't have enough to fill the one column, then we would go to the one below, ... the, the next largest num..., letter after that. Okay?

The inscriptions, which at first served their authors as presentations of parts of the authors' thinking, are now reframed to anchor a collective conversation about the choices that the authors made to carry out key steps. On what basis were these choices made? We see a shift in tone, from more formal presentation to less formal interchange. Where first the inscriptions seemed to organize and tabulate important bits of information, now they help to locate, and make more explicit, lines of reasoning. These lines of reasoning connect important calculation steps to the group's chosen meaning for division: finding a missing factor by reinterpreting the dividend as a suitable product. It is important to note that finding missing factors by filling blanks in multiplication templates looks extremely awkward in place-value arithmetic. Our students took advantage of important special features of their *additive* number system in order to invent their method.

### Conclusions

Our data suggest ways that the construction of inscriptions can help to trigger mathematical discoveries, and also facilitate communication, through the ways in which inscriptions are designed and then interpreted. Our analysis suggests in some detail how inscriptions can begin as presentations, to oneself (or to a few collaborators) of parts of one's own thoughts, but then may be reinterpreted (in effect restructured) to serve the later purpose of communication to a larger group. In the student discourse we report, communication emphasizes *reasoning* to justify conclusions given, and to explain the *choices* made in finding them. The students we have followed here first build, and then communicate original and quite sophisticated mathematics. Our analysis contributes evidence, as did the first two authors' monograph (Speiser & Walter,

2000) that the mathematical potential of preservice *elementary* teachers may be far greater than is generally assumed. Clearly, given the data here, we need to learn still more about the complex uses of inscriptions, both for solving problems, and, through discourse, for building shared and lasting understanding.

# **PRE-SERVICE MIDDLE-SCHOOL TEACHERS' CONSTRUCTION OF LINEAR EQUATION CONCEPTS THROUGH QUANTITATIVE REASONING**

Leslie Steffe  
The University of Georgia  
lsteffe@coe.uga.edu

Andrew Izsák  
The University of Georgia  
izsak@coe.uga.edu

We report on a semester-long teaching experiment with 16 pre-service middle-school teachers. During the teaching experiment, we developed and refined a sequence of teaching activities that focused on solving linear equations embedded in quantitative situations containing unknowns. We designed the activities to support middle-school students' development of algebraic reasoning, but found that the activities were also challenging for pre-service teachers. In particular, our pre-service teachers had significant difficulties understanding and coordinating the core concepts of division of fractions, linear and area measurement, unknowns, and linear equations. By the end of the teaching experiment, only 7 students demonstrated a deep understanding of linear equations and their solutions. Of these 7, 3 were able to explain solutions to linear equations by operating on length quantities in rigorous ways, and 4 others were able to explain solutions to linear equations by operating on length and area quantities in rigorous ways.

Student learning in algebra is a perennial concern in U.S. mathematics education. In recent international studies, U.S. middle-school students' achievement in algebra lagged behind that of their peers in high-achieving countries (National Center for Education Statistics, 2001b; Peak, 1996). Despite increases in average scores on the National Assessment of Educational Progress (NAEP) exam in 2000, 34% of the nation's eighth graders scored below a "basic" level of performance in mathematics (National Center for Education Statistics, 2001a). Moreover, in response to claims that algebra predicts success in college, there have been recent calls for "algebra for all." For reasons such as these, the RAND Mathematics Study Panel (2002) proposes a research program focused on the teaching and learning of algebra.

Past research on the teaching and learning of school algebra has often emphasized algebra as generalized arithmetic, a problem solving tool, the study of functions, or a language for modeling (Bednarz, Kieran, & Lee, 1996). Past research has also documented student difficulties with each of these perspectives on algebra (Kieran, 1992; Leinhardt, Zaslavsky, & Stein, 1990; Monk & Nemirovsky, 1994; Moschkovich, 1998; Nemirovsky, 1994; Schoenfeld, Smith, & Arcavi, 1993). In summarizing existing research on the teaching and learning of school algebra as of 1992, Kieran (1992) argued that algebra requires new understandings difficult to acquire in part because they are abstract and in part because they can conflict with existing interpretations of symbols that students have developed through years of solving arithmetic problems. Because students must develop algebraic reasoning using their prior understandings,

including their past experiences with arithmetic, Kieran's argument raises practical and theoretical questions about approaches to teaching that can support students' construction of algebraic reasoning.

Further research on the teaching and learning of algebraic concepts and algebraic reasoning in the elementary and middle grades is pressing not only because of U.S. student performance in international studies and the RAND report, but also because the *Principles and Standards for School Mathematics* (The National Council of Teachers of Mathematics, 2000) state that an algebra strand should start in the elementary grades and have increased emphasis particularly in the middle grades. Our research focuses on preparing middle-school teachers to teach early algebraic concepts and operations. We report on an initial teaching experiment in which pre-service teachers were the students. During the teaching experiment, we developed and refined a sequence of teaching activities that focused on solving problems about quantitative situations containing unknowns, and we used the activities as a means of exploring the teaching constraints and affordances that the 16 students presented to us as we engaged them in the activities.

### Theoretical Framework

We regard quantitative reasoning as the basis for algebraic reasoning. Thompson (1994) characterized quantitative reasoning in terms of *quantities* and *quantitative operations*. A quantity is a scheme consisting of an object, a property of that object, and an appropriate unit or dimension with which to measure that property. Quantitative operations are mental operations by which one forms new quantities in relation to one or more already-conceived quantities. Thompson (1994) pointed out that quantitative operations are not the same as numerical operations used to evaluate quantities. For the present study, we take *algebraic reasoning* to be quantitative reasoning about constant and varying unknowns. For a student to reason with *quantitative unknowns*, they must have both a scheme consisting of an object, a property of that object, and an appropriate unit of measurement, and the ability to imagine the result of that measurement, even if it cannot actually be completed.

At its core, our teaching experiment focused on solving linear equations of the form:

$$\frac{a}{b}x = \frac{c}{d} \quad (1)$$

We restricted our examples to ones in which  $a$ ,  $b$ ,  $c$ , and  $d$  were integers. At the beginning of our teaching experiment, the pre-service middle-school teachers could solve such equations using an "invert and multiply" rule, but they could not explain why the rule worked. We consider such solutions to be arithmetic at best, because one multiplies two known quantities,  $\frac{b}{a}$  and  $\frac{c}{d}$ . Ma (1999) reported similar results in her study of elementary-school teachers. In our teaching experiment, we tried to support

our students' reasoning about length and area quantities to solve such equations. The examples we discuss in this paper show that such solutions require operating with quantitative unknowns and thus require algebraic reasoning. Thus, our course emphasized the coordination of core, and difficult to learn, concepts including division of fractions, linear and area measurement, unknowns, and linear equations.

### **Methods and Data**

Our research was based on a whole-class teaching experiment (Cobb, 2000; Steffe & Thompson, 2000) with a class of 14 college seniors and 2 masters degree students studying to be middle-school mathematics teachers. The students were enrolled in a semester-long course we taught on the teaching of algebra to middle-school students. During each class we posed problems to students, gave students time to work on the problems either individually or with a partner, and then had whole-class discussions during which students presented and discussed their solution methods, including any drawn representations that they may have used. We circulated and talked to students when they were working alone or with a partner to get a sense of how students were thinking about the problems and the strategies that they were using. At the beginning of the course, students solved problems using pencil and paper. During the second half of the course, students solved problems using Geometer's Sketchpad. We introduced Geometer's Sketchpad so that students could construct dynamic representations of varying length and area quantities. After each class we (the two teacher-researchers) discussed what had happened, hypothesized about aspects of problems and solutions that students did and did not understand, and planned activities for the next class to test those hypotheses. Our results emerged from our interactions with students during class and our analyses of students' written homework, Geometer's Sketchpad files, and exams.

### **Analysis and Results**

The pre-service teachers in our teaching experiment faced significant challenges when trying to solve Equation (1) with understanding. In particular, our students had significant difficulties understanding and coordinating the core concepts of division of fractions, linear and area measurement, unknowns, and linear equations. By the end of the teaching experiment, only 7 students demonstrated a deep understanding of linear equations and their solutions. Of these 7, 3 were able to explain solutions to linear equations by operating on length quantities in rigorous ways, and 4 others were able to explain solutions to linear equations by operating on length and area quantities in rigorous ways.

One of our paradigmatic activities was to find the length of a segment if  $\frac{2}{3}$ <sup>rd</sup>s of the segment was  $\frac{5}{7}$  cm. In an early phase of the course, students made sketches of the situation and, through whole-class discussions, adopted the sketch in Figure 1 as conventional. The graphical representation for  $(\frac{2}{3})x$  was produced by positing a

*hypothetical* segment of length  $x$  cm., taking  $2/3^{\text{rds}}$  as an operation on that segment, and equating the resulting length with a second segment known to be  $5/7$  cm. Positing an unknown length, operating on that length by taking  $2/3^{\text{rds}}$  of it, and equating the result to a known length proved difficult for our students, initially. Nevertheless, through whole-class discussions, students developed an understanding of this first step of an algebraic solution to Equation (1).

To complete the solution, students had to partition the segment of length  $5/7$  cm. into two parts and then iterate one of those two parts three times to produce the segment of length  $15/14$  cm. At first, finding one half of the  $5/7$  cm. length was difficult for our students. They could imagine cutting the  $5/7$  cm. length into two equal parts, but were unsure what the resulting length would be. Through whole

class discussions, the students came to understand that they could find the length by dividing each of the five  $1/7$  cm. lengths into two  $1/14$  cm. lengths and that five of the  $1/14$  cm. lengths was the same length as half of the  $5/7$  cm. length. Once the students understood how to determine that half of the  $5/7$  cm. length was  $5/14$  cm., they could then iterate that length three times to arrive at the final length of  $15/14$  cm., which was also the length of the original segment,  $x$  cm. This constituted a novel way of dividing fractions for the students, and we judged from in-class explanations and homework that at least some of the students learned how to solve linear equations in this way.

We hypothesized, however, that for some of the students who did learn to solve linear equations as explained above, the underlying quantitative reasoning was restricted to the linear situation shown in Figure 1. To test our hypothesis, we had students solve the same  $(2/3)x = 5/7$  equation using *lengths of sides* and *areas of rectangles*. We had students draw rectangles in Geometer's Sketchpad to facilitate their construction of varying quantities. Figure 2 contains a typical sketch of a unit square, the lower left vertex was at the origin of the coordinate plane. By moving the point  $x$  on the  $x$ -axis, students could illustrate the variable length quantity,  $x$  cm., and the variable area quantity,

Figure 1. A linear representation for  $(2/3)x = 5/7$ .

Figure 2. A Geometer's Sketchpad sketch of a unit square and a variable rectangle of area  $(2/3)x$  cm<sup>2</sup>.

$(2/3)x \text{ cm}^2$ , for themselves. To solve, students had to locate the length  $x \text{ cm}$ , so that area of the shaded rectangle in Figure 2 was  $5/7 \text{ cm}^2$ .

### A Final Exam Question

On the final exam, we gave the item in Figure 2 along with the representation shown in Figure 3 because the students had used this kind of representation in class when working on similar activities. The text of the question asked:

Use the sketch to find the value of  $x$  when  $(2/3) \cdot x = 5/7$ . Be sure to write your answer in fractional form and explain how you produced it. In your explanation, be sure to explain the logic in how to solve the equation.

Figure 3. Placing  $x$  so that  $(2/3)x \text{ cm}^2$  was equal to  $5/7 \text{ cm}^2$ .

Students' responses varied from those exhibiting no quantitative reasoning, to those involving arithmetic quantitative reasoning (reasoning in which all quantities except the final answer are known), to those involving algebraic quantitative reasoning (reasoning that involves operating on unknown quantities). The paragraphs below summarize students' responses.

### Non-quantitative or Arithmetic Quantitative Reasoning

Three students simply stated that  $x$  was  $15/14$  based on their prior knowledge to invert and multiply when solving such equations. These students did not give any further explanation of their solution. We characterize these responses as non-quantitative reasoning because none of the numbers was explicitly linked to a length or area quantity.

Three other students used arithmetic quantitative reasoning based on quotative division. One of these students constructed the representation shown in Figure 4 and gave the following ambiguous explanation:

One could rephrase this question and ask how many times will  $2/3$ 's go into  $5/7$ 's. One can see by looking at the drawing that in  $5/7$ 's there are 21 possible areas (we think the student meant that there are 21 sub-rectangles in the unit square). Take  $2/3$ 's of that and you have 14 possible areas. When trying to put  $2/3$ 's into  $5/7$ 's you could only 15 shaded 14ths [sic] will fit in the drawing shown below (we think the student meant that 15 of the 14 sub-rectangles in  $2/3$ 's fit into  $5/7$ ). This would make your answer:  $15/14$ .

Figure 4. One student's arithmetic quantitative solution.

Thus, this student focused on the 21 subdivisions of the unit square and then compared the 14 subdivisions of  $2/3\text{cm}^2$  to the 15 subdivisions of  $5/7\text{cm}^2$ . Just how the student understood connections between the number of subdivisions in the two rectangles and her final answer of  $15/14$ ths remained unclear, but she may have provided an a posteriori explanation using her concept of quotitive division for the answer she knew must be right. The second student in this category also used her concept of quotitive division appropriately when finding how many times  $2/3$ 's would go into  $5/7$ 's, but the third student did not reorganize his whole number concept of quotitive division in situations involving fractions. In fact, there was strong indication in other parts of the course that he had not constructed the concept of an unknown.

### Algebraic Reasoning

Of the students who used algebraic reasoning, three gave solid, correct explanations in which all quantities were linear, as in Figure 1, but not in the case where area was involved, as in Figure 3. Thus they appeared not to have reconstructed their algebraic thinking in contexts that used both length and area quantities. Four other students compared a common subdivision of  $2/3$ 's and  $5/7$ 's explicitly linked to area. The difference between these four students and the student whose work is shown in Figure 4 was that they began by constructing the rectangle of area  $(2/3)x\text{cm}^2$ , understood that  $(2/3)x$  referred to the area of a representative of all rectangles that could be made by moving  $x$  along the  $x$ -axis, and asked what length  $x$  would give the same area as  $5/7\text{cm}^2$ . Thus, these students made clear distinctions between length and area units. These students solved the task of Figure 3 by connecting the four pairs of numbered sub-rectangles as shown in Figure 5. Thus, they matched each of four sub-rectangles in the top row of  $5/7\text{cm}^2$  to four sub-rectangles in  $2/3$ 's  $\text{cm}^2$ . Because there was a fifth

sub-rectangle in the top row of  $5/7 \text{ cm}^2$ , the students knew at this point that the value of  $x$  was greater than 1 cm. The students used the fifth shaded subdivision in the top row to determine that that  $x$  was  $1/14^{\text{th}}$  cm more than 1 cm, or  $15/14^{\text{th}}$  cm. Thus  $(2/3) \text{ cm} \cdot (15/14) \text{ cm} = 5/7 \text{ cm}^2$ .

Figure 5. Four students' algebraic quantitative solution [numbers on subdivisions added].

### Discussion

Although students' difficulty understanding division of fractions is legendary, only rarely has this difficulty been connected to constraints on subsequent paths by which students can construct solutions to linear equations. If emphasis is placed on students constructing solutions to linear equations, careful attention needs to be given to the kind of mathematical thinking that is involved in such constructive activity. In particular, solving Equation (1) through quantitative reasoning requires operating on unknown quantities. Thompson's (1994) view of quantity involves a unit to measure a property of some object. In the case of lengths, constructing a quantitative unknown entails generating an image of a segment and a posited unit length with which to measure the segment. Positing such measurement assumes that the student has constructed a sequence of such unit lengths that can be used to partition the segment, and that the unit length can be iterated enough times to make a new segment of equal length to the original segment (Steffe, 2002). Such reasoning is fundamental to the solution shown in Figure 1 and Figure 5.

The concept of quantitative unknown helps us explain why the distinction that four students made between linear and area units in representing the product of two fractions was so significant. We hypothesize that these students were able to construct the quotient of two fractions using area situations because they could consider  $x$  as a quantitative unknown; that is, they could consider  $x$  to be the result of measuring a segment in terms of a unit length. These students could then posit the product of  $2/3$  and  $x$  as the product of two lengths and ask when this product was  $5/7$  cm<sup>2</sup>. Thus these students could operate on the result of measuring  $x$  in terms of a unit length without actually carrying out that measurement.

The equations and sample solutions discussed above illustrate that about one third (five) of the pre-service middle-school teachers in our teaching experiment had developed relatively deep understanding of Equation (1) in the context of length and area quantities by the end of our semester-long course. At the same time, about one quarter (four) of our students did not exhibit such abilities on the final exam. The remaining students (seven) fell in the middle—they could construct solutions to Equation (1) using situations that contained just length quantities, but they could not yet do so using situations that contained both length and area quantities. This observation indicates that approximately  $5/12^{\text{th}}$ s of students had learned to operate as if they had constructed the quantitative operations necessary for producing the quantity symbolized by  $x$  in the equation  $(2/3)x = 5/7$ . But they didn't seem to understand why operating in the particular they did operate was a matter of logical necessity. That is, they didn't seem to be able to reflect on the way they operated and take it as input for analysis.

The finding that some teachers' understanding of fractions, and division of fractions in particular, is superficial is consistent with other findings like those reported by Ma (1999) for elementary-school teachers. We argue that teachers' difficulties with fractions constrain not only their teaching of arithmetic topics, but also the paths by which they can support their students' learning of core algebraic topics, including solutions to linear equations.

The teaching experiment reported in this study contributes centrally to the goals of PME-NA by shedding light on the opportunities and challenges of using quantitative problem situations to support pre-service middle-school teachers as they develop deep understandings of algebraic concepts that they will be asked to teach as standards-based instructional materials make their way in to middle-school classrooms. By deep understanding of algebraic concepts, we mean the ability to operate on known and unknown quantities to solve equations without resorting to the application of a numeric rule, such as "invert and multiply." The teaching activities that we used in our teaching experiment were designed not only for use by us with our pre-service teachers but also, potentially, for our pre-service teachers to use with their own middle-school students in the future.

# **A PRELIMINARY LOOK AT THE DEVELOPMENT OF BEGINNING MATHEMATICS TEACHERS ACROSS MULTIPLE COMMUNITIES**

Laura R. Van Zoes  
Western Michigan University  
laura.vanzoest@wmich.edu

Jeffrey V. Bohl  
Battle Creek Area Mathematics  
& Science Center  
jeff.bohl@bcmssc.k12.mi.us

An instance where the internship of a secondary school mathematics teacher education student was roughly aligned with her methods coursework and her own beliefs about mathematics teaching provided the context for this analysis of the developing identity of a beginning mathematics teacher. The analysis draws on both situativity theories and established ideas about what is important for teachers to learn by combining Wenger's conception of identity development as learning within communities of practice with Shulman's heuristic of important teacher knowledge in a unit of analysis that we call mathematics teacher identity. The case study points to positive effects from involving prospective teachers in multiple communities where individuals share a common goal of reforming instruction. Specifically, such interaction can nurture aspects of the prospective teachers' mathematics teacher identities that are oriented toward reform, and thus assist them in developing into capable, confident, and committed reformers.

## **Introduction**

Learning to teach involves the coalescing of an individual's history of interacting in a variety of communities playing other roles—student in the classrooms of one's own schooling, student in academic teacher education communities, and intern in another teacher's classroom—into a new role as professional teacher in its various attendant contexts (Bohl & Van Zoest, 2001). How teacher educators can best promote the development of reform-oriented teachers given these multiple influential factors remains an unsolved puzzle.

Much is known about the negative influences of interning in environments that compel interns to conform to a non-reform status quo (Cohen, 1991; Frykholm, 1995; Graham, 1997; Zeichner & Liston, 1987). Until quite recently, this negative impact of status quo contexts was exacerbated by the dearth of reform-oriented teachers working in reform-supportive schools where interns could be placed. The advent of reform curricula and professional development to implement those curricula has benefited the situation. Recent evidence suggests that professional development that supports curricular and policy changes results in classroom modifications leading to increased student achievement (Cohen & Hill, 2000). This study investigates the developing identity of a beginning mathematics teacher who participated in several reform-supportive communities.

### Theoretical Framework

Our theoretical framework draws on situativity theories and on established ideas about knowledge that is important for teachers to learn. In particular, we combine Wenger's (1998) conception of identity development as learning within communities of practice with Shulman's (1987) heuristic of important teacher knowledge in a unit of analysis that we call *mathematics teacher identity* (Bohl & Van Zoest, in press). This model of identity combines (a) the knowledge in a person's head, (b) the communities in which individuals participate and the perceptions of people in those communities, and (c) the beliefs, commitments, and intentions that are stretched between the individual and those communities. *Self-in-mind* is a combination of one's knowledge and one's beliefs/commitments/intentions. *Self-in-community* is a combination of one's beliefs/commitments/intentions and one's perceptions of him- or herself in participation (see Figure 1). We use the term knowledge to refer to ideas that are more or less universally socially accepted and thus not open for public debate. We refer to ideas that are not universally held and thus are subject to public debate as beliefs. Commitments and intentions encompass one's desires to either act or not in response to particular situations, as well as impetus and justifications for doing so. We take learning to be the development of self-in-mind and self-in-community, and we focus on a condensed version of Shulman's (1987) list of important teacher knowledge: content/curriculum (what is to be taught), pedagogical (who is to be taught and how they should be taught), and professional participation (how to interact productively in the communities outside of the classroom that are concerned with teaching). Our distinction between, and subsequent combination of, the in-the-brain and social factors of learning allows the study of a broader swath of the cognitive-social continuum of personal development than is normally considered in research on teachers.

### Methods

This is a case study of "Alice," a student in a reform-oriented secondary school mathematics education program who interned at a school using the Core-Plus Mathematics Project (CPMP) reform curricula. The site was chosen because it provided the best available opportunity to study an instance where the internship of a secondary school mathematics teacher education student was roughly aligned with her methods coursework and her own beliefs about mathematics teaching. In particular, the faculty at the school had developed a sense of professional community where the atmosphere was generally one of communal support for professional growth and curricular reform.

Data for this study were collected prior to, throughout, and following the internship studied. They include: interviews during the internship with Alice (II1-II6), her mentor (MI1, MI2) and Alice and her mentor together (JI1-JI4); planning sessions between Alice and her mentor (P1-P8); classroom observations followed by interviews (CI1-CI4); Alice's journal entries (J1-J25); and her audiotaped reflections (R)

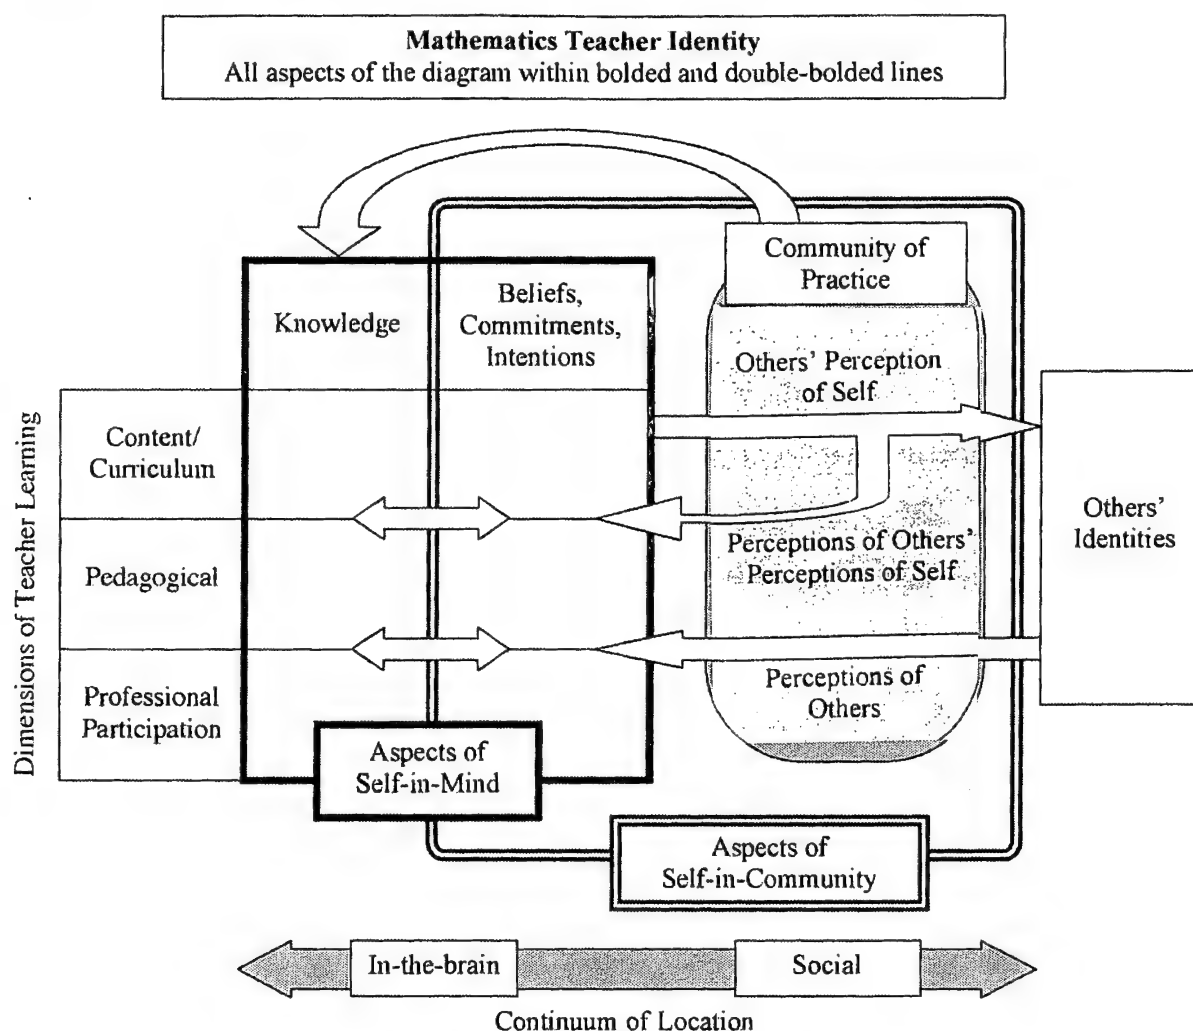

Figure 1. Identity as combination of aspects of self-in-mind and aspects of self-in-community (Bohl & Van Zoest, in press).

and an interview (PI) during her first teaching position. All data except the videotaped observations were transcribed and entered into a qualitative data analysis computer program (*NUD•IST*). The data was coded using indicators (Brown & Dowling, 1998) that mapped to the key components of the Mathematics Teacher Identity framework. The indicators were developed as the data was analyzed and were refined to reflect emerging issues and relationships.

### Evidence

Alice began her internship with a sense of excitement and idealism that was quickly tempered by the realities of the classroom:

I was able to help a few students today when they were doing group work. It felt really good but I can tell that I am not really secure with myself yet. I

feel very unsure of my abilities and of the course material. Yet I know that I have a good foundation of knowledge for both. Somehow I always find myself wanting to check the answer book first before helping a student. I don't think I am ready to handle letting things 'flow where they want.' I want an open classroom with new alternatives but I still need to know where the world is headed. It's like hanging onto a thread of control as fiercely as I can. (J1, 62-78)

This quote encompasses many of the arenas in which Alice developed as a mathematics teacher and captures some of the tension she experienced among her knowledge; beliefs, commitments, and intentions; and perceptions. From the beginning she had a vision of herself as a reform mathematics teacher. However, throughout the internship she struggled with what that meant and how to make it a reality. In the following, we provide a glimpse into the development of Alice's identity along the three dimensions of teacher learning through her participation in several pro-reform mathematics education communities.

### **Content/Curricular Dimension**

Alice characterized herself as an "ideal student" in secondary school who took advanced classes. She had been particularly successful in mathematics. However, she had a revelation during her undergraduate work when she realized that although she had always earned good grades in mathematics courses, she actually had developed very little deep understanding of the content of those courses. She had, rather, learned processes for arriving at correct answers without understanding the mathematics behind the processes. At that point she began to commit to reform in mathematics education, and made it a personal goal to teach her own students so as to enhance their understanding as well as their performance. This aspect of her self-in-mind dovetailed with her self-in-community as this commitment was supported by her three mathematics methods courses in at least two ways: 1) they gave her the opportunity to experience for herself learning mathematics for understanding, and 2) they provided information about curricular materials designed to develop student understanding.

During Alice's internship, the use of the CPMP materials and her mentor's and school's support of teaching for understanding reinforced her experiences in her coursework. Despite this overall resonance, however, some incoherence appeared in the details of implementing reform. We concentrate here on the way in which Alice's learning of mathematics during her internship created some dissonance between her self-in-mind (knowledge and beliefs/commitments/intentions) concerning the learning of mathematics and her self-in-community (those same beliefs/commitments/intentions and her and others' perceptions) regarding the same concerns.

At the beginning of the study, Alice was asked to describe the "perfect internship." She said that it should be:

Not just about learning how to be a good teacher, but [the interns] learning to make the connections in the curriculum that they've never made before. That they're still learning, so that they get a sense that they're always learning about the material. Because I know that I don't go in pretending that I know everything about math. (II1, 304-310)

There were many examples of how her internship, and particularly the use of the CPMP curriculum, created the context for Alice to continue to learn more mathematics (Van Zoest & Bohl, in press). The newness of some of the topics meant that Alice and her mentor were together learning and clarifying the mathematical content for themselves. More often, though, it was Alice who was insecure in her content knowledge. In these cases, her mentor served as her teacher. The following excerpts, the first from an investigation dealing with percentiles and the second with developing mathematical models for scheduling, give a flavor of these interchanges:

I: Now when you say like 40 percent or 40th percentile, cause I get a little bit confused and I just have to go through it. Is it correct to say that you are taller [pause]

M: than 40 percent of the students. And 60 percent of the students are taller than you. Now that can be a little bit misleading because it probably should be 40 percent are as tall or shorter than you, [pause] and [it could be] 60 percent are as tall or taller than you. (P1, 211-220)

\*\*\*

M: See the earliest I can start task B is 3 days, the latest I can start it is 6 days, so that I have it done. Now this one, the earliest and latest are one and the same. But this task here I've got a choice.

I: Right.

M: Because I really have 3 days to play with that I can hold off starting this, because it's only going to take 6 days.

I: So that [pause] okay, so you're earliest start time would be 3. Your slack time is 3. And the latest start time is 6. Okay.

M: In a critical path you don't have any choices. (P2, 1906-1921)

In most instances in which Alice's mentor was helping her to clarify her mathematical understanding his approach was more directive than facilitative. His lack of use of questions in these interactions was in direct contrast to the way in which he and Alice approached their planning and their classroom teaching (Van Zoest & Bohl, in press). As a result, the way in which Alice learned mathematics during her internship was more reminiscent of her own experiences as a student in mathematics classrooms than the investigative experiences that she intended for her students to have or that she had experienced in her mathematics methods courses.

Confounding her mentor's directive approach to teaching her was Alice's resistance to engaging with the mathematics in favor of focusing on issues of teaching the mathematics. Although she desired to help students understand mathematics better by engaging them with it, she apparently did not see a need to engage with it herself. In contrast, she perceived that her mentor was interested in the mathematics. Alice reflected on the differences between them and the confusion it was causing her:

I think that we may end up teaching a lot alike but for different reasons. He looks more into the math part of things while I seem to be more concerned with the "how to learn this math" and "how to manage" kind of things. I just don't know anymore; I feel so confused. (J13, 208-213)

This difference particularly frustrated her when she perceived it leading to over-emphasis on the mathematics during their planning sessions:

... he was more concerned with, "well does this power model fit it [better] with  $1/x^2$ , or is the  $1/x^3$  [better]?" To me, I wasn't concerned about which one was actually better, I just wanted [the students] to be doing it. So it's hard because I get impatient because I really want to know how to teach it. (II4, 496-501)

The researcher's perception was that Alice and her mentor had similar goals, but that the mentor was not successful in making his goals clear to Alice and Alice was not experienced enough to understand that focusing on the mathematics can lead to understanding how to teach it. There is no evidence that Alice and her mentor discussed their difference in approaches to the mathematics or the problems it caused her. This tension between Alice's self-in-community (the mismatch between her and her mentor's perceptions of the role of teachers' engagement with mathematics) and self-in-mind (the dissonance between her beliefs/commitments/intentions regarding her students' learning of mathematics and that of her own) consumed a large amount of Alice's energy and, in particular, many of her journal entries.

### **Pedagogical Dimension**

Two examples of Alice's development along the pedagogical dimension stand out from the analysis. The first involves her struggle to operationalize her perception of teacher as facilitator:

I just don't know how to become that wonderful facilitator, yet give them enough direction so that every kid can see what steps are what so that they can't say, 'Well you didn't write that down. You didn't go over that in class.' That type of a thing. I don't know. I just don't know what it is that I need to fix. (CI2, 127-133)

One approach that Alice and her mentor tried was to break classroom investigations into short series of problems. They structured their classes so that the students

worked in small groups on one or two problems for a fairly short period of time (generally less than ten minutes), and then participated in a whole-class discussion about their solutions. Observations documented that doing this minimized the investigative nature of the curriculum by focusing students on completing the problems instead of making connections among the mathematical ideas within them. Alice was uncomfortable with results of this “experiment” and listed it as one of the things she wanted to modify: “Like with the stopping and starting. I need to figure out some way that they will work in groups and get the work done” (CI3, 196-197).

In an example of negotiating their joint practice, Alice and her mentor re-evaluated their approach and shifted to allowing the students more time to investigate. Alice considered this a watershed moment for her and described what happened:

When we let them work for 20 minutes or so and then brought them back and go through things, things went so much better. They were so much more attentive and they seemed to have better questions to ask. Instead of when we broke it up into ‘here’s one problem, here’s another problem.’ That just doesn’t work well. (PI, 998-1004)

The second example of Alice’s development along the pedagogical dimension involves the more specific issue of using questioning as a pedagogical technique. Alice had learned about the importance of questioning to reform teaching in her methods courses. This resonated with her own experiences, thus she incorporated it into her self-in-mind. However, despite her commitment to teaching using questions, she found it difficult:

[T]he thing that I am unsure of is learning how to draw what you want them to understand, out of them, through questions. Because it’s so easy to be directive with them, but I want them to come up with the answers. (P1, 585-589)

In her journals Alice made many references indicating a conscious effort to improve her questioning. Her efforts were supported by her mentor who, despite his 31 years prior experience, refers to himself as being in the same place as she (i.e., as a learner) relative to reform teaching:

I think the main thing that we both struggle with is we still haven’t gotten to the point where we are letting the students do enough. We’re still doing too much directed teaching and not enough of getting them totally engaged in the discovery process and coming up with; but I think, again, that’s just going to come with time. And practice. And again, a lot of it is just learning with time and experience those questions to ask that are going to solicit that response that we need to get from them. It’s so much easier to just tell them. And the problem with that obviously is generally speaking they don’t learn it from being told. (P3, 456-467)

The recorded conversations of Alice and her mentor are filled with references to their shared commitment to questioning as a teaching technique and their efforts to improve their questioning. This congruence between Alice's self-in-mind and self-in-community both encouraged her to continue to improve and comforted her when she wasn't as successful as she had hoped. It fortified her personal commitment and allowed her to "know" she was capable of improving. Toward the end of the experience Alice noted that she was feeling more at ease "being able to think while I'm up there," specifically as related to formulating productive questions in response to students' questions and their answers to questions (P7, 426-426). Her mentor's evaluations and our observations of her classroom corroborate her perceptions.

### **Professional Participation Dimension**

A key goal of Alice's final of three methods courses was to introduce the prospective teachers to participation in a community of mathematics teachers. The class itself was designed to function as such a community with the students working together as colleagues on projects related to the teaching and learning of mathematics for understanding. Beyond that, they were required to attend a conference on mathematics education and opportunities were provided for them to interact with experienced teachers who were in the process of reforming their mathematics teaching. Alice excelled in this course and incorporated many of the ideas about reform mathematics teaching into her self-in-mind.

By design, Alice's intern teaching placement reinforced the experiences that she'd had in her methods courses. She was able to see things that she had learned about in other communities—such as the CPMP curriculum and a focus on understanding—in action. She described one of the unintended consequences of this as she reflected back on her internship:

I kind of look back on [intern teaching] and say, wow, those teachers were really together and they were very progressive and they wanted a lot of changes. I mean, they really, really liked Core-Plus mathematics. I don't think I realized how, umm, how great of a situation I was, I just never knew it could be anything different. I mean, that was the way it was for me and for some naive reason I thought that it was that way everywhere—that all teachers wanted, you know, all these great reforms and new math and things like that. (J26, 16-26)

Alice's first teaching position, as a semester-long substitute in a middle school, made it clear that that was not the case. At her new school, a senior colleague was a vocal challenger to reform. He opposed changing what he perceived to be successful traditional approaches to mathematics instruction. In particular, he admonished Alice to stick with the skill worksheets that her predecessor had used and not to try anything new. After she mentioned to him that she had intern taught in a CPMP classroom, she

quoted him as approaching her the next day to say, “Well, I just want to let you know that I don’t think that you should do any of that fancy stuff because parents might question your ability and your background. And these kids really need structure” (PI, 131-134). When this teacher disparaged reform mathematics curricula in the teacher’s lounge in Alice’s presence, the other teachers seemed to support his views. This made her uncomfortable because, although she didn’t agree, she didn’t want to antagonize her new colleagues. It also confused her because she observed that the other departments were very much involved with improving their teaching in ways that paralleled the mathematics reform movement. It seemed to her that the mathematics department didn’t fit with the rest of the school—that somehow people believed that math was different from other subjects and kids weren’t able to engage with it in the same ways.

During this time Alice maintained her connection with her internship school as well as with some of her colleagues from the university. Her district was also part of a large National Science Foundation-funded Local Systemic Change Project. This allowed her the opportunity to interact with teachers from other schools in her district who were using reform curricula and who wanted to see changes made in her middle school. This encouragement, fortified by the support of one administrator in her school, served to counter the discouragement she received from her middle school colleagues. With the backing of this broader community of practice, she worked hard to create the kinds of experiences for her students that a reform curriculum would have provided. Alice attributed her willingness to undertake this type of reform to the knowledge and confidence she had gained during her internship. Specifically, she felt that because of her experiences her “opinions [about reform mathematics instruction] are worth something” (II6, 1525-1526)—an example of the strength of her self-in-community regarding reform teaching. She held her experiences with the CPMP curriculum as exemplars of good reform teaching and learning, and utilized them as a baseline for comparison with the curriculum she was developing.

Alice’s mentor predicted that she would have this kind of influence and attributed it to the environment in which she had interned:

Over all it was just an awesome experience. Because Alice is ready to deal with change. She did learn change. She doesn’t know that but she did learn what change is all about this year. I think she saw a lot of change. She will go on and do wonderful things. (MI2, 783-787)

In the years since, Alice has continued to play the role of mathematics education reformer at her middle school. Partly as a result of her considerable effort to align the middle school’s curriculum with its high school’s CPMP sequence, her school is now piloting the Connected Mathematics Project (CMP) materials. These materials are also aligned with the NCTM Standards, and Alice played a key role in convincing her administration that CMP would serve its students well.

### Discussion

Here we will use the mathematics teacher identity framework (Bohl & Van Zoest, in press) to interpret the evidence collected about Alice's development across the dimensions of teacher knowledge as she participated in multiple communities in route to becoming a teacher.

Education students and intern teachers are peripheral (Lave & Wenger, 1991) members of the education community. That is, they are not party to the entire practice of teaching. Moving developing teachers toward the center of the teaching practice is the primary justification for the internship. Central to any practice is the very act of defining, along with other central participants, the practice itself. This "joint negotiation of practice" (Wenger, 1998, p. 84) is the process by which those involved determine how to best do the job at hand. In this case, Alice was given ample opportunity to learn about and participate in this process across multiple communities. Her university course work made her aware of the new and changing theories about how mathematics should be taught. In her contact with the local reform community, she was exposed to teachers who actively identified themselves with the role of negotiating the job of teaching mathematics. Further, her mentor identified openly not only as a learner of his practice, but also as an active participant in figuring out how to do his long-held job better. In the episode where Alice and her mentor experimented with the length of group work during classroom investigations, she had the opportunity to figure out for herself how to best implement in an actual classroom community the theories she had taken on as part of her self-in-mind. This exposure to the negotiating of what it means to teach mathematics from early on in her education seemed to help her understand both change and learning as natural parts of effective teaching. This combination of practice and community support also seems to have allowed Alice to build her knowledge base regarding what works and what doesn't, and to substantiate her beliefs, commitments, and intentions regarding her identity as a reformer.

Another central aspect of a community of practice is its "regime of mutual accountability" (Wenger, 1998, p. 81). This is the set of goals and standards (both written and unwritten) by which people within a practice judge their own and others' performances with a community. Alice realized that she had not really understood much of the mathematics at which she had succeeded, and decided that she wanted to teach for understanding. In this realization she found perhaps the first and most powerful common ground between her own beliefs, commitments, and intentions and those of the reform mathematics community of which she was just then becoming aware. From that point on, she was exposed throughout several communities to other standards, beliefs, and goals related to reform mathematics, and numerous individuals who were striving to teach within those parameters. Included among these was her mentor, who allowed her to participate with him (although not always successfully) in a joint effort to live within the reform regime of accountability. Their commitment to

that regime is indicated by their responses to their failures, which was to critique their own performances rather than to question the overriding goals of reform.

Moving from a focus on the effects of the broader communities to a more specific focus on Alice's participation with her mentor highlights some tension in Alice's development worth examining. One of the primary aspects of mathematics teacher identity is one's perceptions of oneself and of others' perceptions within the community. Generally, in cases where Alice perceived that her and her mentor's goals were aligned, she made fairly smooth and steady progress towards increasing her knowledge base, and her beliefs, commitments, and intentions were maintained, and perhaps bolstered. By contrast, in instances where Alice perceived some dissonance, she was forced to rethink her beliefs, commitments, and intentions. As an example, in the case of substantiating the role of teacher as facilitator, Alice understood that both she and her mentor agreed on its importance. Thus, Alice was able to both resolve (in the immediate sense) the dissonance caused by the failure of class discussion to go as planned, and to contribute to her knowledge base by experimenting with different approaches and monitoring their success. On the other hand, regarding the importance of learning mathematics, Alice perceived that she and her mentor were working at cross-purposes. In this case, the development of both components of her self-in-mind seemed to be limited, as she never connected the importance of her students engaging with the mathematics with doing the mathematics herself. The main difference between these two examples was Alice's perceptions of her mentor's perception of the situation. Although from the researcher's vantage the mentor and intern's goals and commitments in both examples had the potential to be compatible, the intern perceived resonance in the first instance and dissonance in the second. The impact of this difference in perception on her ability to develop highlights the influence a community of practice can have on one's self-in-mind. It also points to the importance of attending to perceptions during intern teaching and reconciling them when they might interfere with the intern's ability to learn.

In the end, although Alice would not realize it until later, the dovetailing of her mathematics teacher identity self-in-mind with the regime of accountability of reformers, and her ongoing exposure to others committed to it, had a major impact in terms of solidifying her commitment to reform. Alice's ability to act on her reform-oriented beliefs and intentions despite a local community focused on maintaining the status quo attests to this. The strength of Alice's developing self-in-mind combined with her increasing identification with, and active participation in, broader reform-oriented communities of practice allowed her to become an agent of change in a situation where it would have been much easier for a new teacher to simply toe the line despite her own beliefs. This contrasts with the common and well-documented responses of interns either modifying their own selves-in-mind or simply accepting discontinuities between their selves-in-mind and selves-in community.

### Conclusions

Through the combination of opportunities to become involved in the negotiation of the practice and early and on-going participation with others who subscribed to a similar set of beliefs, commitments and goals, Alice enhanced her mathematics teacher identity as a reformer. This included strengthening her content and pedagogical knowledge, fortifying her beliefs and commitments concerning reformed teaching, and developing a perception of herself as a potentially successful reformer within the community of mathematics teachers. Reform-oriented mathematics teacher identities are fundamental to sustained improvement of mathematics education. Although research has demonstrated that a reform-based teacher preparation program is not sufficient to generate this type of identity in beginning teachers (e.g., Frykholm, 1995; Parmalee, 1992), it does appear that aligning the internship with reform-based university coursework, in combination with engaging the intern in a broader reform community, has the potential to do so. This study highlights the importance of involving prospective teachers in communities that share a common goal of reforming and of investing resources in developing such communities. When this happens, aspects of prospective teachers' mathematics teacher identities that are pre-disposed to reform are nurtured and can influence their future actions as teachers and supporters of reform. In particular, teaching competence, commitment to teaching for understanding, and confidence as a reformer can all be enhanced.

## **USING RESEARCH ON CHILDREN'S COGNITION TO ENHANCE PRESERVICE TEACHERS' KNOWLEDGE OF DIVISION**

Peter S. Wiles  
University of Arizona  
wiles@math.arizona.edu

In this study, I examined the knowledge of prospective elementary teachers who participated in a mathematics course where considerations of content were driven by examples of the development of children's thinking. Using resources derived from the Cognitively Guided Instruction project, students in the course examined the mathematical ideas inherent to children's thinking. My analysis of interviews conducted at the end of the course revealed that my students not only tended to emphasize conceptual ideas rather than just procedures, they also placed a high premium on developing this kind of understanding in their future pupils. After a brief discussion of the context of the course, I will present some of the data that illuminate the strengths and limitations of my students' knowledge.

### **Background**

In the past decade, there has been widespread concern about the subject matter preparation of teachers of mathematics. Much of the research on teachers' knowledge has focused on their level of knowledge in various mathematical domains and the influence their knowledge has on their teaching practice. It has become evident that while teachers may be proficient at performing mathematical tasks, many do not possess an understanding of the conceptual aspects of the content that they are teaching, even at the primary grades (Ball, 1991). There is evidence to show that teachers with less developed subject matter knowledge tend to focus primarily on mathematical procedures rather than the concepts underlying them. Without a strong understanding of the mathematics, such teachers were not able to adequately respond to children's questions or novel ideas (Leinhardt & Smith, 1985; Stein, Baxtor & Leinhardt, 1990). Little research has been conducted to examine how to help teachers strengthen their mathematical knowledge.

At the university level, teacher educators are faced with the challenge to provide programs for future teachers to help them develop the mathematical knowledge that they will need. Recently, there have been recommendations that teacher education programs actively engage preservice teachers in the mathematics of the elementary curriculum (Conference Board of the Mathematical Sciences, 2000; National Research Council, 2001). Traditionally, it has been thought that the content of the elementary curriculum is easy and requires little attention at the university level. Programs for future teachers emphasized advanced mathematics coursework in order to deepen their subject matter understanding. It has been found, however, that many students who had advanced coursework at the university level still had difficulty explaining the conceptual aspects of the fundamental ideas of elementary mathematics (Ball,

1991). As a consequence, many teachers entered their practice not having examined the material they are to teach since they themselves first learned it. Programs that do not explicitly examine the mathematics of the primary grades risk sending out teachers who are ill prepared to meet the demands of current reform agendas.

### **Subject Matter Knowledge for Teaching**

It has become recognized that the knowledge base required for teaching must be conceptualized in a much different way than it is in other mathematical professions (Shulman, 1987). Rather than compacting ideas together to facilitate their use in other endeavors, a teacher must be able to unpack ideas in such a way as to facilitate learning (Ball & Bass, 2000). Teachers must be able to examine the fundamental components of a mathematical idea and make connections to other mathematical ideas and the trajectory of the curriculum (Ma, 1999). Typically, math courses do not engage students in this kind of activity. Courses for prospective elementary teachers need to help teachers to develop a flexible conceptual understanding of the mathematics they are to teach.

While it seems that a conceptual understanding of the mathematics is a key element of a teacher's knowledge base, it alone is not sufficient. In order for their knowledge to be useful for teaching, a teachers' mathematical knowledge must be developed in tandem with their knowledge of learners and pedagogy. A teacher must use their mathematical knowledge to anticipate and evaluate students' ideas or misconceptions and be sensitive to the ways that children learn about mathematical ideas. To be relevant, the mathematics that future teachers engage in should be situated within the context in which it will be used Brown, Collins, & Duguid, 1989).

### **Description of the Project**

This paper will highlight a portion of a study that sought to examine the impact on teachers' knowledge of using research about children's thinking as a major component in a mathematics content course for prospective elementary teachers. The subject area that I will focus on in this study is division. Division serves as an important bridge to the development of rational number understanding. It has been observed, however, that prospective teachers come to their teacher education programs with a fragmented understanding of division (Ball, 1990).

This course was the first of three content courses required for elementary education majors at a large Midwestern university. There were 36 students in the two sections of this course taught by the author. During the units on number operations, I engaged the students in video and written material developed from the Cognitively Guided Instruction (CGI) project (Carpenter, et al., 1999). As this was a content course and not a methods course, I directed the students attention primarily to the mathematical ideas inherent to children's thinking. Much of the students' time with division was spent examining the differences between partitive and measurement division situations

and their influences on children's strategies. The students also spent time examining the mathematics behind children's invented strategies for solving division problems.

### **Data Collection**

Throughout the semester, I kept copies of all the students' written work as well as my own field notes and journal entries. I consistently reviewed these materials as the semester progressed. Near the end of the semester, individual clinical interviews were conducted in order to obtain a picture of their mathematical knowledge. Due to scheduling problems and technical difficulties, only 27 of the students in the course were interviewed. The questions for the interview were adapted from those developed by Deborah Ball (1990). For this paper, I will only discuss the results from the questions involving the division concept. The students were first asked to tell how they would respond to a child's question about what division by zero is. Second, they were asked to solve and provide a representation for a division problem involving fractions. Each student's responses were probed to obtain a picture of their conceptual understanding of the subject. As the problem situations were in a teaching context, I also probed to ascertain their thoughts about teaching these ideas.

### **Results**

After several rounds of analysis, a three level scale was developed into which each student was placed. This was done twice, once with regard to the students' conceptual understanding of the material, and once with regard to their perceptions of how these ideas might be taught.

#### **Knowledge of Division by Zero**

The students' responses to the hypothetical child's question about the answer to the problem seven divided by zero fell into one of three categories. The students were sorted into the levels accordingly if they were unable to provide an answer (level 1), created an accurate representation but were unable to correctly interpret it (level 2), or for accurately explaining the problem (level 3).

##### **Level One**

Students whose responses were at level one were either unable to provide an answer to the problem, or recalled the answer but were unable to provide an explanation for their answer. Of the 27 students interviewed, 10 (37%) were placed at this level. Only two of these students correctly identified division by zero as being undefined. When asked to explain, they could not offer a response. The other students relied on incorrectly remembered rules such as "anything divided by zero is zero".

##### **Level Two**

Students at level two were able to create a representation that correctly modeled division by zero, however when probed, they were unable to correctly interpret what

the representation meant. Four students (15%) gave responses at this level. Two of the students provided a representation consistent with a partitive division model. In this model a set of size seven is to be placed equally into zero groups. Since there are no groups, it is impossible to say how much each group gets. When asked about their representation, both students became confused and reinterpreted the situation as being multiplication with zero groups of seven or seven groups of zero. The other two students provided measurement representations where one asks for the number of sets of size zero inside a set of size seven. Both students created representations where zero is being taken out of seven but mistakenly interpreted the answer to be zero because nothing is being taken away.

### **Level Three**

The remaining 13 (48%) of the interviewed students were placed at level three for accurately explaining why division by zero is undefined. All but two of these students explained the problem through a word problem. Six of the students described a partitive division situation. While the situation that they offered was correct, few of these students were able to provide a precise interpretation of the situation and corresponding answer. Many of these students recognized that this representation might be confusing with the answer interpreted as being zero. Two students talked in detail about the difficulty. Both recognized that they needed to get across the idea that since there are no groups to partition into, it is impossible for the partitioning to take place in the first place. Five students offered measurement division models. The students offering this representation had less difficulty interpreting the answer. Two of these students thought about the problem in terms of collecting a number of zeros to make seven. The other three thought in terms of breaking up seven into groups of zero.

The last two students at level three did not rely on word problems to explain their solution. One student made use instead of the relationship division has with multiplication. She explained that you could not multiply any number by zero to come up with an answer of seven. The other student relied on thinking about division by zero as a limiting process, explaining that as you divide by smaller amounts, the quotient becomes larger.

### **Teaching Division by Zero**

The students were also probed to discuss how they would handle the situation should one of their students ask such a question. As with their knowledge, the responses were placed into one of three levels. The students either emphasized telling rules (level 1), giving an explanation of the concepts (level 2), or engaging the child in the mathematical ideas (level 3).

### **Level One**

At level one, the students felt that it would be the most productive to tell the student the (sometimes erroneously stated) rule. At issue for many of these students was

their perception that young children would not be able to understand an explanation. While some students indicated that this idea might be able to be explained at a higher grades, they still felt that it would be best to not risk confusion. One student, Jenna, expressed:

Then, when you get older you say it is undefined or something. If they were young enough, I would just say it was zero. I don't know, try not to confuse them. I don't even know what it is all about.

Similarly, Kirstin believed that young children would not be able to understand:

I think at an age, like sixth grade age or elementary age and you're learning the easier addition, subtraction, multiplication and division, you don't even think to ask why. It is kind of just there for you to look at and believe. I don't think at an elementary age you are taught to ask why.

At issue for many of these students was their own inability to understand the content. As a result, these students felt it would be best to avoid the idea completely.

### **Level Two**

Of the 27 students, 16 (59%) talked about wanting to try to explain the concept to the child in one way or another. These students were classified at level 2. In each case, the emphasized their desire to help the child make sense of the problem. None of these students indicated that they would try to engage to child to work on the problem on his or her own or with other children. There was some variability in the ways that the students indicated they would explain. Two of the students appealed to completely erroneous explanations, like misinterpreting the relationship between division and multiplication. While their explanations were incorrect, they appealed to more than just a remembered rule. Some of the students remarked that they would make use of counters or pictures to help the child visualize the division process. Others indicated that they would use a story problem to put their explanation in context. None of these students indicated that they would use the word problem as a device to encourage exploration on the part of the children.

### **Level Three**

The remaining four students were placed at level three. Like the students at level two, these students talked about their desire to help the child make sense of the problem. Rather than just providing a model for the child, these students also indicated that they would engage the children into thinking about the problem on their own. A primary characteristic of their responses was their intention to probe the student for his or her own understanding. For example, Helen responded:

I guess I would first ask them what they thought and then be like, present a different division problem and see if they could point out the similarities. And if they couldn't, see why they can't.

While these students indicated that they would try to help the child through questioning, their inexperience with children inhibited their ability to be specific about what they would ask or what kinds of responses they might anticipate.

### **Knowledge of Division of Fractions**

The second interview question under consideration involved creating a representation for the division problem  $1\frac{3}{4}$  divided by  $\frac{1}{2}$ . While creating representations can be thought of as a pedagogical activity, it is also inherently mathematical. If one is to create a context to model a mathematical idea, one needs to have an understanding of how that mathematical idea fits together. In this instance, one must have an understanding of both division and rational number concepts. As with division by zero, the students' responses were placed into one of three levels based on whether they were unable to provide a correct representation (level 1), provided an inappropriate representation (level 2), or provided an accurate representation (level 3)..

#### **Level One**

Seven students (26%) were categorized at level one. These students were either unable to provide a representation or they provided a representation that did not model the division problem. Two students were unable to any word problem for the division problem. Of these, one was unable to provide an answer to the problem either. Many of the students mistakenly created a word problem for division by two rather than division by a half. None of the students who solved the problem correctly were concerned that the word problem would result in a different answer. One student, Barbara, was fixated on the invert an multiply rule and instead created a story for multiplication by 2. While this gives the same answer as the division problem, the action taking place is quite different. Barbara recognized this, however, and remarked:

I don't see it as dividing by a half, I see it as multiplying by two. So I don't think that I can come up with a problem where dividing by a half makes sense, because I don't see this as dividing by a half.

One student, Tiffany, correctly conceived of division by a half as finding the number of halves in  $1\frac{3}{4}$ , but had difficulty with the rational numbers. Her problem was:

If I need one and three fourths batches of something, and all I have in my cupboard is a half a cup, how many times would I need to fill the half cup to get to one and three fourths batches?

Tiffany confounded the units of the two fractions creating a word problem that cannot be solved.

#### **Level Two**

Responses classified as level two were accurate representations of the division situation, but the context used would suggest an answer other than  $3\frac{1}{2}$ . Three students

(11%) were placed at level two. The problems these students ran into stemmed from the use of units that are not typically thought of as being divisible. Consider Jason's problem: "Well, if we have  $1\frac{3}{4}$  pizza and each person would like to each [have]  $\frac{1}{2}$  of a pizza. How many people can we serve?" In this case, the appropriate answer would just be 3. The two other students used money in the form of coins.

### Level Three

The remaining 17 students (63%) were able to provide an accurate word problem for the division problem. Of these, five students provided a word problem that would fit into a partitive division model. For instance, Emily's problem was, "Betsy had one and three fourths of pizza. This was half of the total amount there was. How many pizzas were there?" When asked why she thought that this word problem was  $1\frac{3}{4}$  divided by  $\frac{1}{2}$ , Emily responded:

If you look at it again with the items and groups thing, then you are going to label on and three fourths as your items and half as your groups. So your items are one and three fourths and that's making up one group which is half of the total. You have half a group here. So what is the one total group?

One of the key benefits of using the partitive model of division is the ease with which one can connect the word problem to the invert and multiply procedure.

Fourteen of the students at level three gave a measurement division problem. For instance, Jackie's problem read: "Say you need one and three fourths cups of sugar for a recipe, and you only have half a cup, so then how many half cups will you need?" Most of the students used measuring devices in their word problems. This context was particularly helpful because as a physical entity, a measuring device can represent both a whole and a fraction at the same time. For instance, a half-cup measuring device could be thought of as half of a one cup unit, or as a whole half cup unit. This ability to flexibly unitize has been found to be an important aspect of learning how to work with rational numbers (Behr, Harel, Post, Lesh, 1992).

### Teaching Division by Fractions

During the interview, the students were asked about how they might teach the division by fractions concept and whether they thought that creating a context for the problem would be important. Three levels were identified very similar to the levels identified for teaching division by zero. The students either emphasized procedures and rules (level 1), emphasized providing clear explanations of the concepts (level 2), or emphasized facilitating exploration (level 3).

### Level One

Six students (22%) gave responses at level one. All of these students indicated that they would prefer to focus on having the children become proficient with the dici-

sion by fractions algorithm. While some of these students thought that word problems might be beneficial, most thought that they would get in the way. They were afraid that a child would not be able to extract the meaning from the wording and would end up making the problem too complex. For them, the worded setting provided extraneous information and distracted from what they saw as the core problem of calculating the answer. Moreover, it was felt that word problems were too time consuming, where classroom time could be better used focusing on repetition and worksheets.

The two students at level one who did see some benefit in using word problems did not do so necessarily to promote conceptual understanding. Instead, these students saw word problems as a way to capture children's attention and motivate the learning of computational procedures. William echoed this point when he stated:

I remember that if I didn't see when I was going to use this stuff, I just tuned out. So maybe they would see the word problem and see how easy it is to do the problem just flipping the fraction.

### **Level Two**

Fifteen of the students (56%) interviewed were placed at level two. While many of these students felt that children should learn the invert and multiply procedure, these students also expressed that it would be important to explain what division by a half means. For these students, the word problems served as useful tools to support the teachers' role in providing explanations to the children. Of these fifteen students, four indicated that word problems alone might be problematic. As with students at level one, they feared that children might get confused with the word problems. Unlike the students at level one, however, these students wanted to do more than just tell the students the invert and multiply rule. Many of these students were concerned that they themselves did not feel that they were given the chance to understand what the procedure meant and felt that they would need to still provide some kind of explanation. Instead of just word problems these students suggested using pictures, activities and demonstrations to illustrate the concepts. Those students who did think that using word problems would be a beneficial way to help children learn the concepts also echoed the sentiment that visualization is important. In each case, the student talked about themselves creating the pictures or models from the word problems.

### **Level Three**

The remaining six students (22%) were placed at level three. These students echoed many of the sentiments espoused by students at level two. Additionally, these students indicated that a primary benefit of using word problems would be their ability to help children develop these conceptions on their own rather than directly from the teacher. Consider Diane's statement:

I think it helps kids use their minds when they think of stuff on their own when they aren't just given a certain way of doing things. I don't think that

teaching is just telling kids how to do that. I think it is helping kids understand why it is they do certain things. Getting them to figure out things on their own.

Similarly, Emily emphasized the importance of allowing children to construct their own meanings:

I think there's a lot to be said, first of all for the creativity, and just why stifle a child's understanding and creativity if they've got a way to do it, if they've got a better way to understand it. It's not really fair that we are forcing something on them.

Both of these students felt that by giving word problems, they could allow children to explore the ideas in their own ways.

The other students emphasized the benefit that word problems would have in classroom discussion. They felt that letting children discuss their solutions to the problems would allow the class to become exposed to different ways of thinking about the problem. Many of the sentiments expressed by these students mimic the structure that I established in the classroom. One student made explicit reference to way that I organized the class around working in groups and sharing strategies with the entire class.

### Discussion

In Deborah Ball's (1990) study of prospective teachers' knowledge of division, only one of ten prospective elementary teachers were able to provide a correct explanation for division by zero. None of these teachers were able to provide a correct representation for division by fractions. In Ball's study, the students predominantly focused on procedures and rules and felt that citing these rules sufficed for an adequate explanation. Liping Ma (1991) reported similar results with inservice teachers. This is a marked contrast to the results presented above. The students in this course appeared to have a much stronger grasp of the conceptual idea of division.

It should be noted that during the course, division by fractions was a topic of study that I had the students engage in. They had been asked to create representations for these problems before. Division by zero, however, was not discussed explicitly. Almost 50% of the students in the study were able to provide a correct explanation for why division by zero is undefined. For most of these students, they were applying their understanding of division models, something that was a topic of emphasis in the course.

While these students focused a great deal on conceptual aspects of the problems, it is clear that there are still gaps in their understandings. These teachers did not evidence the kind of flexible knowledge that Liping Ma (1999) observed in the Chinese teachers of her study. The students in my study generally only offered one strategy for examining the problem. Moreover, my students rarely made connections to other related mathematical ideas. For instance, though many of the students were able to use

their knowledge of division models to guide their explanations, few of the students tried to connect the situation under consideration to multiplication or to division with whole numbers.

One of the central themes of the students stated approaches to teaching was a desire to help children understand what they are doing rather than doing mathematics by rote. While talking about this many of the teachers referred back to their own experiences regretting that they had never had a chance to understand the mathematics. While many of these students emphasized the importance of understanding the ideas behind the mathematical rules, few indicated that this kind of understanding is something that children could construct for themselves. For many of these teachers, their approaches toward teaching was still very teacher centered and directed. It is unclear, then, how long such a focus on conceptual mathematics would last when they are actually teaching. Moreover, there is evidence of a potential source of conflict in the teachers' stated beliefs. With regard to division of fractions, none of the students indicated how their word problem could be used to illuminate the invert and multiply procedure. While they developed an understanding of what division by fractions might mean, none of the students connected it to the procedure. As many of the students also stated that it would be important for children to know the procedure, it is unclear what they might emphasize when teaching this material.

Finally, this study was conducted primarily to try to ascertain the mathematical thinking of students who had experienced a non-traditional class where content and pedagogy were intertwined. Much more research needs to be conducted to ascertain the specific effects of a treatment such as this. Research also needs to be conducted illustrated the long term effects of instructional programs such as this one.

## THE INFLUENCE OF CULTURE ON LOGICAL REASONING

Sunday A. Ajose  
East Carolina University  
ajoses@mail.ecu.edu

This study investigated the impact of culture on logical reasoning. It found evidence indicating that the cultural values and beliefs held by a group of prospective elementary school teachers influenced the way they analyzed and solved two logic problems.

### Introduction

The work of scholars such as Bishop (1988, 1994), Cooney (1985), D'Ambrosio (1985, 1988) and Thompson (1984, 1992) made the mathematics community reconsider some long-held beliefs concerning the relationship between culture and mathematics. What emerged from these studies was a greater understanding of how cultural factors such as language and beliefs affect the practice and outcome of mathematics education. Evidence from these studies show, for example, a strong connection between teachers' beliefs and their pedagogical behavior. Moreover, mathematics educators were made more aware of subtle culture conflicts which some students experience in the classroom, and the effect of these conflicts on the students' participation in mathematics. The present study investigated links between cultural beliefs and logical reasoning among pre-service elementary school teachers.

### Method

The subjects for the study were 39 elementary education majors including one ethnic minority student. The students were enrolled in the third and last mathematics course for their program. The other two mathematics courses treat the content of contemporary K – 8 mathematics at an advanced level; they emphasize reasoning, problem solving, and introduce students to logic. For this study, the students were given the following two logic problems to solve three weeks apart.

1. One of four girls has emptied a cookie jar. These are their statements:  
Alice: "Betsy did it  
Betsy: "Doris did it."  
Candy: "I didn't do it."  
Doris: "Betsy lied when she said I did it."  
If only one statement is true, which of the girls took the cookies?
2. At a party of truth-tellers and liars, you meet a new friend. He tells you that he has overheard a conversation in which a girl revealed her identity, saying she was a liar. Is your new friend a liar or a truth-teller?

The problems, adapted from Fixx (1978, p. 40) were selected because they are fairly simple, and require only deductive reasoning to solve. The students were allowed to use any resource they had in order to complete each assignment. They were asked to describe their thinking about the problem, write down details of their attempts to solve it, whether successful or not, and justify their conclusions. They had a week to work on each problem outside class. After the students had submitted their solutions to each problem, I led the whole class in analyzing some of the submissions, including acceptable solutions, solutions with reasoning errors, as well as some that employed unacceptable or illogical strategies.

All 39 students submitted solutions to the first problem; 38 did the second. The handwritten solutions to each problem were carefully analyzed and classified on the basis of the conclusions and the validity of the supporting arguments. Cultural underpinnings of incorrect solutions and invalid arguments were noted.

### Results

Twelve of the solutions submitted for the first problem were correct. Some of the solutions were quite elegant, and all were based on sound arguments. Eight solutions to the second problem were of the same quality. Thus, less than 33% of the solutions submitted for each problem were based on valid arguments. An analysis of the students' written responses indicated that cultural values and beliefs seemed to hold sway over much of the students' thinking about these problems. It seemed that many of the students approached these problems with a baggage of culturally based premises that made successful solution of the problems virtually impossible. Here are some examples.

In the first problem, some concluded that Betsy emptied the cookie jar, presumably because she had three "strikes" against her, more than any of the other girls. Strike one: she was a suspect in a crime. Strike two: she blamed the crime on somebody else; the justification for this strike was the popular belief that people who accuse others of crimes for which they too are suspects, do so because they "probably have something to hide." The third strike was her failure to deny the claim by Doris that she, Betsy, was a liar. Clearly, this pattern of reasoning has more to do with baseball and popular culture than logic.

Several students used another kind of invalid reasoning to arrive at the correct conclusion that Candy emptied the cookie jar. The students used a process they named "reverse psychology." This procedure called for reversing the statement made by each suspect. Since the reverse of Candy's statement is "I did it", these reverse psychologists needed and sought no further proof that Candy was, indeed, the cookie monster.

In still another set of solutions, some students also came to the right conclusion by employing a type of reasoning often used on multiple-choice exams when the examinee has no clue about a particular question. A student on her 4th attempt at the problem, put it this way. "I looked at the problem like a multiple choice question. Betsy's,

Alice's & Doris' statements all have something in common. They are all attacking another person. So I chose the one choice that didn't have anything in common with the other statements. Therefore, Candy is the one who took the cookies"!

Similar patterns of reasoning, obviously influenced by cultural beliefs and practices, were observed in the solutions to the second problem as well. In one case, students stated that there wasn't enough information to "judge" the new friend. They considered it unfair to judge a guy "so early in a relationship" on the basis of a single, insignificant incident.

In another case, the respondents said the new friend was a truth-teller even though they believed that he was telling "a story" about the girl who supposedly revealed her identity. After all, "nobody tells the truth (or lies) all the time." Consequently, how one judges the new friend "depends on whether you see the good or the bad in people."

Yet, another group of students concluded correctly that the new friend was a liar, again, not on the basis of any logical argument, but rather because he was an "eaves-dropper" and therefore, not trustworthy!

### Conclusion

The results of this study suggest that cultural practices and beliefs do influence some people's ability to reason mathematically. Is the degree of this influence related to the level of the knowledge of mathematics? The data from this study did not provide a clear answer. Although the mathematically strong students in the study sample produced most of the correct solutions, they also supplied some of the unacceptable answers. As I reflected on why many participants in this study were unable to come up with acceptable solutions to the two problems, I remembered what one of them wrote:

"I think that when trying to solve a problem like this, you bring your own experiences and preconceptions to the problem. You base your decision on your own life experiences."

I believe that this quote accurately describes how many other students approached the problems. Faced with two unfamiliar problems that required no computation, many of the students were neither able to put aside their preconceptions, nor base their decisions solely on deductions made from the given data using the rules of logic.

## **EFFECT OF EMBEDDED COTEACHING MODULE ON ATTITUDES OF PRESERVICE ELEMENTARY TEACHERS**

Lisa Carnell  
High Point University  
lcarnell@highpoint.edu

Mariann Tillery  
High Point University  
mtillery@highpoint.edu

The objective of this study was to determine if attitudes of education majors at a four-year university toward inclusionary coteaching practices could be changed by embedding an intensive coteaching module within a mathematics methods course for preservice elementary teachers. The rationale for the study was based on preliminary survey findings obtained in 1999. At that time, students were asked to evaluate their overall attitudes toward inclusion by rating their perceived level of preparation, knowledge, and enthusiasm to coteach in an inclusive general education classroom. General education majors were consistently more neutral for coteaching.

### **Theoretical Framework**

A major focus of national educational reform has been the ongoing effort to include students with disabilities in the least restrictive academic environment. The inclusive education movement, largely fueled by the legislative mandates of the Individuals with Disabilities Education Act (IDEA), requires states to establish procedures to assure that students with disabilities are educated, to the fullest extent possible, in general education classrooms (Lesar, Benner, Habel, & Coleman, 1997). In an inclusion model, special education teachers work alongside of general education teachers to deliver a single merged system of instruction, thereby unleashing the "best of both worlds" (Skrtic, 1996).

Gately and Gately (2001) explain coteaching as an ongoing developmental process whereby skills in interpersonal communication, curriculum, instruction, and assessment are gradually acquired. Fostering the desire for collaboration dialogue takes time (Hargreaves, 1992), and therefore it has been suggested that competencies in coteaching, collaboration, and inclusive instruction may need to be shaped early on during the teacher's preservice educational experience (Webb & Romberg, 1994). Although some of these preservice models described in the literature do indeed show promise (Farlow, Caseau, & Gurlin-Jones, 1996; Lesar et al., 1997; Munby & Hutchinson, 1998), it appears that many students in teacher preparation programs claim that they receive minimal opportunities to observe collaborative teaching in an instructional context.

### **Method**

A three-week intensive coteaching module was embedded into one section ( $n = 13$ ) of a mathematics methods course for preservice elementary teachers at a four-year

liberal arts university. Another section ( $n = 14$ ) of this same course, taught by the same instructor, did not receive the coteaching module and was used as a control group.

During the coteaching module, a university faculty member with a background in special education joined the course instructor. Together they taught the preservice teachers the basic models of coteaching and demonstrated coteaching in practice as they taught course content related to teaching basic arithmetic facts, place-value, and whole number computation for students in elementary school. The control class that did not receive the module on coteaching was taught the same mathematics topics by the course instructor alone.

At the end of the semester, approximately six weeks after the end of the coteaching module, both classes were given a survey to assess knowledge of, preparation for, and enthusiasm toward inclusionary coteaching practices. Using a modified version of the *Teacher Attitudes on Inclusion* developed by Monahan, Marino, and Miller (1996), a 34-item survey allowed students to rank their perceptions of inclusion on a Likert-type scale ranging from (1) strongly disagree to (5) strongly agree. Items taken from the original questionnaire were modified in their wording to be more appropriate for undergraduate students rather than current classroom teachers. Additional items were also added to assess the respondent's overall knowledge of inclusion as a service delivery model. *T*-tests were used to compare the mean scores for the coteaching group and the control group on knowledge of, preparation for, and enthusiasm for inclusionary coteaching practices.

### Results and Conclusions

A comparison of mean scores on survey items concerning attitudes about inclusionary coteaching practices for both the group receiving coteaching instruction and the control group that did not receive coteaching instruction are given in Table 1. There was a statistically significant difference in mean scores in each of the three areas surveyed. The group receiving coteaching instruction had higher mean scores on items relating to knowledge, preparation, and enthusiasm about coteaching. Although it may not be surprising that the sense of knowledge and preparation for coteaching instruction are improved by the mere exposure to inclusionary coteaching practices, perhaps most exciting is the notion that preservice faculty can also directly impact enthusiasm for coteaching.

The objective of this study was to determine if embedding an intensive coteaching module within a mathematics methods course for preservice elementary teachers could change attitudes of education majors at a four-year university toward inclusionary coteaching practices. The results of this study indicate that attitude differences can be made, most markedly in the knowledge and preparation preservice teachers perceive they have for coteaching. To a lesser extent, preservice teachers can also have their enthusiasm and receptivity to coteaching influenced by instruction about coteaching. Since coteaching may be the most effective method of instruction for special educa-

tion students in the inclusion setting, it appears that including coteaching modules in the preparation of preservice teachers may represent best practice.

**Table 1.** Mean Score Comparisons for Knowledge, Preparation, and Enthusiasm for Inclusionary Coteaching Practices for Coteaching Group and Control Group

|                       | Mean | Standard<br>Deviation | <i>t</i> -statistic | p-value |
|-----------------------|------|-----------------------|---------------------|---------|
| Knowledge             |      |                       |                     |         |
| Coteaching            | 4.11 | 0.2447                | 8.30                | < 0.01  |
| Control               | 2.37 | 0.6506                |                     |         |
| Preparation           |      |                       |                     |         |
| Coteaching            | 3.56 | 0.7736                | 4.17                | <0.01   |
| Control               | 2.31 | 0.5474                |                     |         |
| Enthusiasm            |      |                       |                     |         |
| Coteaching            | 4.07 | 0.4305                | 4.23                | <0.01   |
| Control               | 3.38 | 0.3999                |                     |         |
| 1 = strongly disagree |      | 3 = neutral           | 5 = strongly agree  |         |

## **A PRE-SERVICE TEACHER'S GROWTH IN UNDERSTANDING RATIO, PROPORTION AND RATE OF CHANGE USING LESSON PLAN STUDY**

Clarence E. Davis  
North Carolina State University  
ce\_davis@ncsu.edu

Katrina N. Staley  
North Carolina State University  
kstaley@unity.ncsu.edu

### **Focus of Study**

This study is part of an extensive 3-year longitudinal study was to examine the ways in which undergraduates who are preparing to teach high school mathematics come to change their understanding of the high school content through lesson plan study. We were trying to find out in what ways does lesson plan study change pre-service teacher's understanding of ratio, proportion, and rate of change. Berenson, Cavey, Clark, and Staley (2001) stated that teacher preparation needed to include instructional teaching strategies that are associated with the content of high school mathematics. Here we define the content of high school mathematics as topics up to and including Algebra-Trigonometry/ Pre-Calculus class.

### **Conceptual Framework**

The conceptual framework was Pirie and Kieren's model of mathematical understanding. "[T]he growth of mathematical understanding is a whole, dynamic, leveled but non-linear, transcendentally recursive process. This theory attempts to elaborate in detail the constructive definition process of organizing one's knowledge structures"(Pirie & Kieren, 1994, p.166). Descriptions that are relevant from this model include primitive knowledge, image making, image having, formalized knowledge and folding back. More specifically, the Pirie and Kieren theory was used in coding the transcript of the interview. We looked for instances in which the pre-service teacher went through the various stages of the theory and began to change her understanding of ratio, proportion, and rate of change.

### **Methodology**

Karen was a student in her first mathematics education methods course. She participated in two iterations of lesson plan study (LPS) occurring over a 16-week semester. Each iteration of the LPS contained three distinct components. The first component was an individual interaction study that included a preliminary knowledge base interview, a lesson planning activity and a post interview. The second component was a group interaction study, which included a lesson planning activity, a group interview, and a group presentation to their fellow classmates. The final component had the student produce a reconstructed view of their individual lesson plan (Berenson, in press).

Here we report on the results of the first component of Karen's rate of change LPS cycle. She was asked to plan a lesson to introduce the concept of rate of change to an Algebra I class and relate that concept to ratio and proportion. Karen's lesson plan was viewed as acting in context while content competencies were needed to complete the task. The sources of data were transcriptions of two videotaped interviews, student notes of the planned lesson, and descriptive artifacts.

### Results

In the pre-lesson interview, Karen discussed her Primitive Knowledge about ratio, proportion and rate of change in a procedural manner.

#### Ratio

K: "When I think of *ratio*, I think of 2 to 3. Like if you had two of one thing and three of another..."

K: "You have 2 to 3 and 2:3, and sometimes you could write a fraction  $\frac{2}{3}$ ."

#### Proportion

K: "...if you had different *proportions* of things, like if you had 8 red umbrellas and 10 black umbrellas and you wanted to know the proportion of red umbrellas to black umbrellas you would say 4:5"

K: "I think a lot of things deal with *proportion*. You know things being equal to each other."

#### Rate of Change

K: "The only thing I can remember doing with *rate of change* before then was maybe with slope or something. I can't really think of anything, it just reminds me of Calculus."

K: "I think basically if you were doing it to basic kids who had never heard it before, take two *rates*. If you had one rate and another rate and you are going from one to the next and you want to how they changed, you would subtract them from each other or something."

During the post plan interview, Karen described her lesson plan to the interviewer, who then asked clarifying and probing questions concerning her ideas about ratio, proportion, and rate of change. Karen seemed to be in the stage of Image Making when she began to replace her simplistic explanations with reasons for making connections for her students.

K: "Okay. Well before I would go into rate of change or rates, I would talk about ratios and proportions first, because that leads to it."

K: "A ratio is an ordered pair of numbers that are used to express a comparison between the numbers or measures. So it's a comparison of numbers or measures."

At this point Karen seems to Fold Back to her Primitive Knowledge and states, "...I might start with fractions because all fractions are ratios." Later in the interview Karen starts Image Having about how to teach and clarifies her new concept of ratio. Karen began to explain the part-whole and whole-whole relationships when dealing with fractions a concept that she used to help her clarify her new ideas about ratios.

K: "Right. Then I would go into putting up like if you had  $\frac{2}{3}$ . Then you have two parts to three parts of a whole....If you have 3 apples and 2 are red and 1 is green. What is the ratio of red apples to green apples? It's 2 to 1 because you have two red apples to one green apple."

K: "If you have 20 kids in a class, which that's your whole, and 8 are girls and 12 are boys. The 8 that are girls are part of that whole and the 12 that are boys are part of that whole. But now if you were asking the ratio of boys to girls, it is 8:12 [Corrected to 12:8]. That's a ratio that's not a fraction."

After discussing her new ideas about ratios, Karen began to explore the topic of proportions. Karen moved from a stage of Primitive Knowledge in her first explanations of proportions to one where she began Image Making. In this process she began to replace her primitive knowledge with definitions and examples that she felt comfortable discussing.

K: "I would probably say a proportion is a statement of equality between two ratios."

K: "Like if you have a fraction that's  $\frac{6}{10}$  then it is equal to  $\frac{3}{5}$ . That's a proportion,  $\frac{6}{10} = \frac{3}{5}$ ."

K: "...Like if you have four pieces of candy are \$1.00, how much are twelve pieces of candy? And however you set it up, you would say like if you put candy to \$1.00, put candy on top of \$1.00 and that would be equal candy over here over dollars, which would be 12 pieces to how many dollars."

After stating new images of proportion she then Folded Back to her Primitive Knowledge and used other tools to assist her explanations, "Then I would go into cross multiplication you know cross multiply."

The lesson-planning activity appeared to have contributed to her growth of mathematical understanding of ratio and proportion encouraging her to Fold Back a number of times to revise her images. However, Karen's idea of rate of change seemed to remain unchanged.

K: "...but when I think of rate of change, I think of slope, having two rates and

going from one to the next. Or if you have two rates, one's one rates in the same thing. Like if you're in miles per hour and you have one mile per hour, then you go, you speed up to go to the next miles per hour. What was the change in those two rates?"

These results from the lesson-planning task support Towers' (2001) conjecture that students' understanding is partly determined by teacher interventions. Interventions such as lesson-planning activities may allow students to reflect on their own knowledge and build new images. Through these reflections and discussions with colleagues and teachers, students could realize some of their own limitations and misconceptions about how to teach and what it means to teach mathematics.

## BRIDGING THEORY AND PRACTICE IN PRESERVICE MATHEMATICS TEACHER EDUCATION

George Gadanidis  
University of Western Ontario  
ggadanid@uwo.ca

Ann Kajander  
Lakehead University  
akajande@sky.lakeheadu.ca

Ball (1988) notes that the mathematics teaching theory presented in mathematics education courses rarely influences “what university educators do with *their* students. [...] University classes are typically “delivered”, even when they are *about* the problem with delivering knowledge to children in schools. As one teacher remarked wryly, she had been in courses where she got *lectures* on constructivism” (p. 28). It seems reasonable to expect that teacher education courses model the learning theory they espouse.

Constructivists generally agree that knowledge is actively constructed by the learner rather than passively absorbed from the environment. Implying the belief that students actively construct their understanding is the idea that “present strategies for teaching may need to be reversed; knowledge often should emerge from experience with problems” (NCTM 1989). Certainly students construct understanding even in passive lecture settings. However, if we want education students to learn how to recognize, analyze and engage in solving mathematical and pedagogical problems “then their instructional environment should be one where that is what they do” (Greeno, 1988, p. 518). Also, research indicates that for significant change to occur in teachers’ beliefs and practice, teachers need experiences where they engage in practical inquiry and reflection about mathematics and mathematics teaching (McGowen & Davis, 2001; Stipek, Givvin, Salmon, & MacGyvers, 2001).

### Linking a Mathematics Methods Course and Practicum Experiences

The mathematics teacher education course for secondary school preservice teachers described here was based on the assumptions that: 1) teacher agency and personal reform beliefs are an integral part of education reform; 2) teachers learn to use their personal agency in reforming education through experiences where they practice using their personal reform beliefs in their teaching; and, 3) opportunities for reflection promote a dialectic relationship between beliefs and practice. The course involved preservice teachers in outlining their personal mathematics reform beliefs and selecting and becoming more knowledgeable about an area of mathematics education that supported their beliefs (such as computer assisted learning, the use of manipulatives, problem-solving approaches, cooperative learning, etc.). They researched their area of interest, refined personal beliefs, and developed four detailed lesson plans. They implemented at least two of the lesson plans during their practicum (and videotaped one of these) and designed a resource package for other teachers to use.

Preservice teachers also reflected on their beliefs and practice. During the practicum, they kept a weekly journal of their efforts to apply their beliefs to classroom practice. After the practicum, they wrote a narrative of their experience. They also discussed the relationship between their reform beliefs and practice in their analysis of the lesson they videotaped. For many preservice teachers, the practicum is an experience where they put aside their personal beliefs and learn to adapt to the status quo. What they think and believe becomes secondary to existing classroom and school cultures. This course offered preservice teachers opportunities for practicum experiences where they also tried to improve on the status quo.

Confrey (1990, p. 107) lists "the promotion of student autonomy" as one of the components of a constructivist learning environment. However, is teacher agency, and an accompanying focus on teachers' reform beliefs, appropriate for the preservice stage of teachers' professional development? Fuller (1969) identified three stages of concern teachers go through as they learn to teach: survival concerns, teaching style concerns, and pupil concerns. Recognizing that, generally, certain concerns may tend to be more predominant in one stage than another is very helpful in supporting preservice teachers during their practicum experience. However, developmental descriptions of teacher growth are sometimes interpreted in terms of what preservice teachers can or cannot do at each of the stages identified. Such an interpretation questions the view that personal reform beliefs, and an accompanying focus on teacher agency, is an appropriate concern for the majority of teachers in the preservice teaching "stage". Scardamalia and Bereiter (1989, p. 43) concede that a case can be made for omitting such higher-level concerns "in preservice education and introducing them through inservice education, after teachers have passed through the 'survival' and 'mastery' stages and are ready to deal with impact." However, they also note that "it has been shown that once teachers are entrenched in problem-minimizing approaches it is very difficult to dislodge them". In our experience, preservice teachers can and do learn in reform-based settings.

### **Encouraging Investigation and Collaboration in Lecture Settings in Mathematics Courses**

Preservice mathematics courses often take place in large classroom environments which have the potential to contradict the aims of reform-based learning. Encouraging and facilitating the active participation of students in constructing their own learning is necessary to provide students with the opportunity to experiment, self-reflect and interact. Organizing students into learning groups at the beginning of the year can offer them opportunities to work together on an exploratory activity at some point during each class. The groups are also helpful in terms of distributing materials (or returning assignments sorted by group number) quickly. While it may be difficult to have sufficient manipulatives for large classes, the groups can take an active role in constructing their own sets of items such as base ten blocks, fraction bars and algebra tiles. Sugar

cubes make great substitutes for centi-cubes or tiles, and many other activities can be done with home made materials. After investigating, the whole class environment can then be used to share and generalize results. The small groups may also be used as a forum for presentations of individual projects on various topics. Students are asked to submit a proposal for a presentation on a topic in reform-based mathematical learning, which they will present to their group. The students are provided with resources describing reform-based learning and are encouraged in risk-taking and trying new ideas and topics in novel ways. The presentations themselves are graded within the peer group, using checklists developed by each group. Peer grades are submitted anonymously, and averaged, and a participation mark is also given for handing in the peer evaluation forms. All of this detailed evaluation has another important feature – students always come to the ‘lectures’. While there is some recording to be done, this phase has no “marking” to be done by the instructor. The remaining project grade is determined based on a written report with background references on the activity graded by the instructor.

Students claim to enjoy group activities, and it seems to spark a new interest in mathematics and mathematics teaching. In fact, for many students with a history of feeling unsuccessful in mathematics in school, the reform-based experience is both exciting and rewarding. As one student put it recently, “it feels like the first time I’ve taken math.” Students are encouraged to choose a topic they think they will really enjoy working on, however unusual, and topics have ranged from the mathematics of rainbows to the symmetry of the human face (with active group participation of course!). Students also gain first-hand experience in alternative evaluation practices. Often students try to outdo each other with active, fun and engaging topics and creative presentations, and many provide their group members with packages of ready-to-use resources. Similar “special interest groups” can also be used to investigate a particular topic, or create a particular product. An example would be a course resource book prepared by the students on particular topics, such as use of technology.

Pressing students to develop deep understandings of difficult concepts such as division of fractions or subtraction of integers may also require extensive reflection in their learning. The use of journal entries may be helpful in the self-reflection process. Grading can be facilitated for large classes by asking students to choose their best entry (or two) to be marked.

### Conclusion

Preservice mathematics teachers, as is the case with students in general, construct understanding based on *what* they are taught and based on *how* they are taught. We believe our mathematics teaching philosophy should be mirrored in our teacher education practice. We also believe that this is not a simple task.

## **DIDACTICAL ANALYSIS AND PLANNING OF SCHOOL TASKS IN PRESERVICE MATHEMATICS TEACHER TRAINING**

Pedro Gómez  
Universidad de Granada  
pgomez@valnet.es

Luis Rico  
Universidad de Granada  
lrico@ugr.es

In this paper, we propose the didactical analysis as a tool to assist future secondary mathematics teachers in their analysis of mathematics content in order to plan, implement, and assess teaching and learning tasks in class. We propose a conceptual structure that supports the curriculum design of a methods course and present the elements composing the didactical knowledge that we expect preservice teachers to develop in such course.

### **Introduction**

The methods course we are in charge of is taken by last-year mathematics students. It is a theoretically oriented course that is complemented with a second course in which future teachers perform some practical activities in a high school. One of the main goals of our course is to develop preservice teachers' didactical knowledge as the basis for curriculum design at a local level (didactical units). The content of the course is therefore related to the disciplinary knowledge that serves as reference to didactical knowledge: the concept of curriculum, school mathematics, their teaching and learning, and the curriculum organizers. Preservice teachers work in groups of four to six people. Each group chooses a specific mathematical subject on which it develops its curriculum design. This work is periodically and systematically presented, shared, and discussed in class at different levels of development, until the final document is produced. This allows everybody to participate, individually and socially, in the construction of the technical meanings they are using in their own work. In what follows, we introduce the idea of didactical analysis and show its relationship with the notion of didactical knowledge. We show how the content component of the curriculum design of the course is based on these two notions.

### **Didactical Analysis As A Tool For Local Curriculum Design**

The notion of pedagogical content knowledge (Shulman, 1987) highlights that knowledge of mathematics and pedagogy are not sufficient in order to become a mathematics teacher. Teachers need a specific knowledge for understanding "how particular topics, problems or issues are organized, represented, and adapted to the diverse interests and abilities of learners, and presented for instruction" (p. 8). Despite of its importance, this notion has not been treated with precision in the research on teachers' knowledge (Bullough, 2001, p. 657). The issue of which types of knowledge are needed by mathematics teachers in order to be efficient and how this knowledge can be developed remains open and is central in teacher training (Cooney, 1994, p. 608; Richardson, 2002).

The design of a mathematics methods course should be based on a conceptualization of the activities that the teacher has to do in order to promote students' learning and of the knowledge that is necessary to perform those activities. We call the structuring of a cycle of these activities a *didactical analysis*. It is organized around four analyses: content, cognitive, instruction, and performance. Didactical analysis allows the teacher to examine and describe the complexity and multiple meanings of the subject matter, and to design, implement, and assess teaching/learning activities.

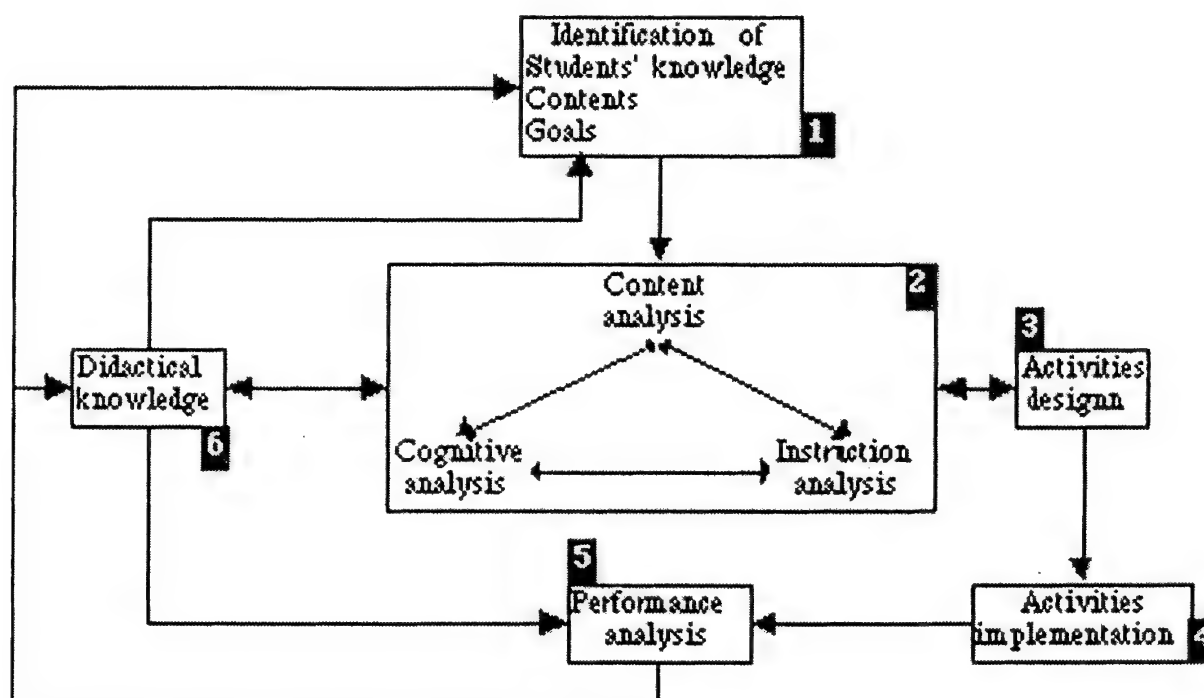

Figure 1. Diagram of a didactical analysis cycle.

Any cycle of the didactical analysis begins with the identification of the student's knowledge for the subject matter at hand (see Figure 1). We expect the teacher to use his knowledge and previous experience for establishing the tasks that the students can and cannot solve, the mistakes they can make, and the difficulties underlying those mistakes. With this information, and taking into account the global planning of her course, we expect the teacher to determine the goals she wants to achieve and the mathematics content she wants to work on (box 1).

The next step of the cycle involves the description of the mathematical content from the viewpoint of its teaching and learning in school (box 2). The *content analysis* stresses the relationship among concepts, highlights its multiple representations, and distinguishes the connections between the elements of the conceptual structure and

between those elements and the phenomena from which they emerge. This information is used in the *cognitive analysis*, in which the teacher describes hypothesis about how students construct their knowledge when they face the learning activities that are proposed to them. The cognitive analysis involves the identification of the skills, reasoning, and strategies necessary to solve the tasks, of the mistakes students can make when they are solving them, and of the difficulties and obstacles they might face. The information from the content and cognitive analysis allows the teacher to carry out an *instruction analysis*: the identification and description of the tasks that can be used in the design of the teaching and learning activities that will compose the instruction in class (box 3). These tasks should mobilize students' knowledge in order to generate cognitive conflicts and promote the construction of meaning using the materials and resources available. In the *performance analysis* the teacher observes, describes, and analyzes students' performance in order to produce better descriptions of their current knowledge and review the planning in order to start a new cycle (box 5).

The *didactical knowledge* is the knowledge that the teacher enacts when she performs the didactical analysis (box 6). In other words, it is the knowledge needed for organizing teaching and learning activities in didactical units. Expert teachers perform didactical analysis based on their experience and the materials they have available. However, preservice teachers need guidelines and criteria with which to organize their activities, produce their work, and structure their future experience. The didactical analysis provides guidelines for preservice teachers to 1) explore and recognize the richness and variety of meanings of the mathematics subject matter, 2) collect, organize and select information concerning these multiple meanings, and 3) use this information to design materials and activities to promote students' mathematical learning. The knowledge underlying these guidelines can be organized in three categories: 1) the concept of curriculum as a tool for planning and global structuring, 2) the foundations of school mathematics (mathematics, learning, teaching, and assessment), and 3) mathematics education notions that can be used, as conceptual and methodological tools, for local planning, as suggested in the cycle of didactical analysis. We call these notions "curriculum organizers" (Rico et. al, 1997): conceptual structure, representation systems, didactical phenomenology, modeling, errors and difficulties, materials and resources, and problem solving. Didactical knowledge is the integration of these three types of knowledge.

## COMBINING CGI WITH WORKING WITH CHILDREN: EXAMINING REFLECTIONS OF PRESERVICE TEACHERS

Beth Herbel-Eisenmann  
OISE/UT  
bhe@oise.utoronto.ca

This paper examines some of the learning experiences of 43 undergraduate preservice teachers in two pilot sections of an elementary math/science methods<sup>1</sup> course. Vinz (1996) argues that it is worth asking: "What do teachers reflect upon and what forms does that reflection take?" (p. 84). I explore this question, focusing mainly on one learning activity used in the course. In this learning activity, preservice teachers work in pairs and are assigned a small group of four to six second-grade children with whom to interact in regular elementary school classrooms. As teaching partners, the preservice teachers are required to: (1) develop/use a set of problem solving tasks that build on children's thinking and ideas (drawing mainly from the Cognitively Guided Instruction framework (CGI) (Carpenter, Fennema, Franke, Levi, & Empson, 1999)), (2) engage the children with the problems and audio tape the interaction, (3) listen to the audio tape and write a structured reflective journal,<sup>2</sup> and (4) use information they learned from the reflection to develop and justify the next set of problem solving tasks to pose.

The structured reflective journals consisted of four parts,<sup>3</sup> which I use to report my preliminary findings below. Because the structured reflective journal defined *what* the preservice teachers focus on, I examine *how* they reflected on these areas. The corpus of data collected include weekly written structured reflective journals, audio-taped class sessions, observations made by collaborating experienced teachers and myself, transcripts from a focus group interview that took place at the end of the semester, and final case studies prepared by the preservice teachers which describe the 2<sup>nd</sup> graders' content, processes, and attitude development over the course of the semester. For this manuscript, I present preliminary findings after having analyzed the structured reflective journals and final case studies. Further analysis over the summer will produce a more complete picture of the findings reported here.

### **Describing the Mathematical Content in the Problems Posed**

Many preservice teachers easily classified the operations (addition, subtraction, multiplication, division) in the problems they posed. In fact, they drew from the problem structures described in the CGI framework and often identified the correct operation, even though the problem could be solved with a different operation. For instance, if a problem was a Join-Change Unknown problem, subtraction could be used to solve the problem even though the structure of the problem, as written was addition. Students sometimes used the problem type to label the operations rather than stating the

operation itself. Identifying when base ten was a prominent idea was more difficult for many of the preservice teachers. For example, many students did not distinguish between problems that required regrouping and those that did not. Because we had viewed an experienced CGI teacher on a videotape using groups of ten in division problems as one way to integrate base ten with division, many of my students were able to recognize problems of that type as including the concept of base ten.

**Collecting Data<sup>4</sup> on Each Child's Content, Processes and Attitudes (Cantlon, 1994; National Council of Teachers of Mathematics [NCTM], 2000).**

Preservice teachers attended carefully to the children's attitudes, and this became the most prominent piece in the case studies they wrote. Many preservice teachers began the semester by making general statements (e.g., "they all used blocks") about the children's mathematical processes, but became more attuned to them both through observing the children and through reacting to comments I wrote on their reflective journals. They often recorded the language and actions the children used when describing their solution strategies as evidence that a child was using a particular solution strategy. However, some preservice teachers used, "he said he did it in his head," as evidence that a child used "derived facts" rather than pushing the child to articulate *how* s/he did it in his/her head.

The area that was the most difficult for preservice teachers to address was the content piece. Much of what they recorded (under the "content" section) pertained to processes (e.g., communication skills) and attitudes (e.g., "he focused and tried hard"). While the processes and content are overlapping areas (and we discussed this at length in class), the connection between them was often not identified in the reflective journals, even when I asked about it in my written feedback. Some students did make this connection in the case studies they wrote; others did not.

**Examining the Interaction That Too Place (e.g., the questions they asked and how they followed them up, the maintenance or decline the cognitive complexity (Stein & Smith, 1998) of the tasks they posed)**

Most of the preservice teachers used the course readings and ideas to examine their interactions with the children in insightful ways. For example, some expressed dissatisfaction with the way that they stepped in and did the problems for the children if they were struggling because they realized they reduced the cognitive demand of the high level tasks that they had written (see Stein & Smith, 1998, for this reflection framework). Other preservice teachers focused on trying to show me that they were doing it "right" by defending what they did. Most of the preservice teachers did ask open-ended questions that focused on helping the children articulate and explain their thinking, rather than mainly asking "teacher questions."

### **Describing Other Items About Which They Noticed or Wondered**

In this more open-ended section of the journal many of the preservice teachers focused on concerns about the children, e.g., how the children felt about having other children explain solutions to them if they couldn't solve the problem. They also expressed concerns about teaching, e.g., how to support the children in articulating their own thinking or how to work with such varied levels of engagement and understanding of the content.

These preliminary findings support Nicol's (1999) findings. The preservice teachers in this study were able to attend to the mathematics, instructional issues, and children's thinking in their work with second-grade children. Some of the aspects with which the preservice teachers struggled are problematic (e.g., not seeing the connection between identified processes and what that means to the children's mathematical understandings). However, as a teacher educator, I see these areas as ones that I need to address in the course, not weaknesses of the preservice teachers.

### **Notes**

<sup>1</sup>The class is called a "methods" class, but that term seems to indicate that there are a series of activities that one might learn to teach math in an 'appropriate' way. I prefer to focus on teaching as a reflective activity in which one makes informed decisions about what s/he will do, drawing on his/her own experiences, experiences of others and on pertinent literature related to what is being taught.

<sup>2</sup>I use "structured reflective journal" to indicate that the items preservice teachers are required to reflect on are determined by the questions I pose rather than being more extemporaneous.

<sup>3</sup>The parts to the journal were developed based on Nicol's (1999) observations and literature related to *experienced* teachers using CGI. Nicols found that preservice teachers *were* able to consider and attend concurrently to concerns of management, student's mathematics, and instructional issues.

<sup>4</sup>The data collected by preservice teachers was used to write detailed case studies for the classroom teachers, focusing on each child's content, processes, and attitudes.

## THINKING ABOUT UNIVERSITY MATHEMATICS TEACHING: FORMAL ASSESSMENT AS INTERACTION

Karen D. King  
Michigan State University  
kdking@math.msu.edu

The purpose of this paper is to examine the instruction of one university mathematics faculty member in his effort to implement a capstone mathematics course for preservice secondary mathematics teachers. The faculty member, Dr. Jeffords (a pseudonym), had as one of his overarching goals to teach a course in accordance with the recommendations of various organizations (Conference Board of the Mathematical Sciences, 2001). One of the major recommendations of these documents and programs was that preservice teachers experience mathematics in ways that are similar to the ways that they are being asked to teach: student-centered; focused on student learning and connections to classroom teaching; connected the content to the practice of teaching; and used technology. In this paper, I examine, using Simon's (1995, 1997) Mathematics Teaching Cycle, the ways in which the assessments given in this course influenced Dr. Jeffords' goals, interactions with the preservice teachers and knowledge for teaching a course of this type.

### Theoretical and Analytic Framework

I used the Mathematics Teaching Cycle [MTC] (Simon, 1997) as a theoretical and analytic framework for guiding data collection and analysis. In brief, the MTC describes the iterative process that is a model for teaching. In this process, the teacher develops a *hypothetical learning trajectory*, a combination of the teacher's goals, which inform the teacher's plan for achieving these goals also informing and informed by the teacher's hypothesis about how students learn. These plans are then enacted with students to allow for interactions with students, leading to changes in the teacher's knowledge of the students, their mathematics, his own mathematics, and other types of knowledge necessary for teaching. This knowledge then cycles back to inform the teacher's goal, hypothesis for students learning and plan.

This cycle can be used describe a particular episode in a class as well as weeks of classroom instruction. For the purposes of this brief report, the cycle will be used to model a more global aspect of Dr. Jeffords' instruction, the ways in which his evaluation of assessments serve as an opportunity for interactions with students in ways that impacts both the teacher's knowledge of the students' mathematics and his goals and plans for and enactment of instruction.

### Data Collection

I collected data during the Fall 2001 semester at a large midwestern university in the US. Dr. Jeffords, a Caucasian male, is a tenured mathematics educator in the mathematics department at this university. The class, a capstone course designated for

senior-level preservice secondary mathematics teachers, also served as an upper-division writing course as part of the university's writing across the curriculum program. During the semester, I interviewed Dr. Jeffords both immediately before and immediately after each class period. I also attended, as an observer, each class period and took copious notes, along with a graduate assistant. Two undergraduates videotaped the class using digital video cameras, one focusing on the teacher and the other focusing on the students. When students worked in groups, the camera focusing on the teacher followed the teacher's movements through the class, the other focused on one group of students. I also collected all student work that was submitted to the teacher, after Dr. Jeffords had graded the papers and/or provided feedback.

### **Data Analysis and Results**

#### **Dr. Jeffords' Initial Goals**

For analysis, I examined the Dr. Jeffords' plans for the class, as well the interview data to classify his goals for each class period, as well as overarching goals that were always present. A goal that Dr. Jeffords expressed as important was that the preservice teachers begin to frame their own mathematical questions, pursue these questions, and communicate their responses in ways that would be useful to other teachers. Dr. Jeffords stated in an interview that he wanted students to begin to ask themselves the questions "What is the mathematics in this situation? Where does it lead? How do we get there?" (Interview, 8/28)

#### **Dr. Jeffords' Hypothesized Learning Path and Formal Assessment as Interaction**

Dr. Jeffords initially hypothesized that by presenting students with a mathematically rich context and helping them to formulate mathematical questions to pursue, he and the preservice teachers would begin to address his goal. Difficulties arose, however, as students had difficulties formulating mathematical questions, as opposed to more science-oriented or education-oriented questions from rich contexts.

In addition to interactions with preservice teachers in the classroom, Dr. Jeffords' evaluation of the their Mathematics Investigation for Teachers Journals was a form of interaction with the preservice teachers. As Dr. Jeffords explained it, the students were to pursue a mathematical topic of interest to them and write an explanation of their findings, with other teachers as the intended audience. This assessment task was in keeping with his goal that the preservice teachers should develop their own mathematical questions and pursue them and the writing goals of the course.

From students' early journals, Dr. Jeffords felt they had difficulty in framing mathematical questions and pursuing them mathematically, particularly questions that were different from questions already pursued in classes. In the beginning of the semester, Dr. Jeffords would provide contexts for the journals. After the class' first journal entry, he engaged the students in attempting to develop a rubric for the journal

that focused on asking an appropriate mathematically based question and pursuing the question sufficiently. The students also focused on the aspects of communication, such as using appropriate representations and clear writing.

Dr. Jeffords and the students recognized that they had difficulties with meeting his expectations for the journal assignments. During one interview, he explained why he was going to discuss the journals during class time. He felt that “most didn’t pursue mathematics and of those interested in math, it wasn’t really investigated. Or they stopped at the initial solution” (Interview, 9/11). He communicated this issue of framing mathematical questions and pursuing the question in mathematical ways to students, but they continued to have difficulties. For example, at a point at which the students had done two journals and had questions about how to determine what was a good question and how to pursue a question “deeply” one student, Susie (pseudonym) asked a question about “How deep is deep?” (Class Observation, 9/13). Dr. Jeffords focused his discussion on moving toward mathematical generalization and proof, answering in ways consistent with a senior-level mathematics major. Later in the semester, this same student, who often acted as a spokesperson for the class, asked Dr. Jeffords to give examples of generalizing a topic (Class Observation, 10/25).

### **Changes in Dr. Jeffords’ Knowledge and its Influences**

Dr. Jeffords came to recognize that his model of the preservice teachers’ mathematics did take into account that the preservice teachers had difficulties with the process standards of representation, reasoning and justification, communication, and problem formulation as part of problem solving. He also came to understand that the students had constructed both mathematics and mathematical communications through previous and current interactions in other mathematics courses in the department. Thus, Dr. Jeffords’ plans for attaining his mathematical goals changed. Through the MIT Journal entries, he refined the task by asking the preservice teachers to begin focusing on generalizing ideas from secondary mathematics (Interview, Class Observation 9/27). Additionally, he added a weekly assignment in which the students worked in groups to present to their classmates investigations from a reform secondary mathematics curriculum, focusing on particular connections to undergraduate mathematics (Interview, Class Observation 9/27). Dr. Jeffords created additional assessment opportunities to interact with his students and their mathematics.

### **Discussion**

The MTC operates as a theoretical lens to observe the moves in Dr. Jeffords’ teaching over the course of the semester. Dr. Jeffords reassessed his understanding of the preservice teachers’ mathematical knowledge and their identities as mathematics students, thus impacting his ways of achieving his goals, illuminating a larger issue. In many classes, assessment does not inform instruction, only operating as summative evaluation of student knowledge. Often faculty do not view assessment as a lens into

the students' beliefs about mathematics and themselves as students of mathematics, potentially impacting overt discussions of the assessment practices involved in the course. This analysis shows how formal assessment can be used to inform instruction as interaction with students in the MTC. Assessment, particularly in secondary and post-secondary courses where work done outside of class is expected to be a major contribution to students' learning, becomes an important site for examining instruction and impacting faculty professional development.

## **PRESERVICE TEACHERS' PART-WHOLE CONCEPT UNDERSTANDING: TWO EXAMPLES**

Dorothea Arne Steinke  
NumberWorks  
steinkedb@earthlink.net

An earlier study (Steinke, 1999) reported that, in a ten minute non-paper-and-pencil assessment, 2 of 15 preservice teachers showed lack of part-whole concept understanding in answering a question of the form: If I have 25 circles altogether, and 7 circles are on the plate (visible), how many circles are here (hidden)? This article explains how their manner of responding identified these students as lacking part-whole concept understanding and what this implies for those involved in teacher education.

Even with solid, NCTM-Standards-based instruction in their math methods and/or math content courses, some preservice teachers (PSTs) fail to achieve a level of understanding such that they feel capable of teaching mathematics in other than a procedural manner (McGowen & Davis, 2001; Raymond, 1997; Thompson, 1992). Many studies have focused on teachers' or PSTs' grasp of rational number, division, or geometry. There is evidence, however, that some PSTs lack the earlier, more fundamental concepts of place value (Ross, 2001) and the part-whole relationship (Steinke, 1999).

Steinke's 1999 study reported that two of fifteen volunteers from a math methods class for PSTs did not show part-whole concept understanding when given a non-paper-and-pencil assessment in a videotaped interview. Only the raw data, in terms of correct and incorrect responses, were given in that paper. However, it is the behavior of the interviewees as much as, or even more than, their answers that reveals their thinking about numbers.

Steffe and Cobb's (1988) 3 Stages model of number sense development in young children (Perceptual, Figurative, Abstract) is the framework for the interview questions. Not until the Abstract Stage do children understand that the parts and the whole always coexist, allowing them to solve with ease "missing addend" or "missing part" problems ( $P[\text{art}] + ? = W[\text{hole}]$ ) beyond the range of memorized addition and subtraction facts.

The assessment used with the PSTs is the one originally developed for and administered more than 700 times to over 300 children (Steinke, 2001) over a period of 8 years. The test has also been administered to over 100 adults. The behaviors of the non-Abstract Stage adults are virtually identical to that of non-Abstract Stage children.

The assessment begins with Perceptual Stage questions ( $P+P=?$ ) using two sets of visible objects, then proceeds to Figurative Stage questions ( $P+P=?$ ) with one set of visible objects and a written numeral. Finally the questions are switched to the form  $P+?=W$  (Abstract Stage) with the Part a set of visible objects and the Whole a written numeral. To ensure that the interviewee, child or adult, catches the change in

question form, the first Abstract Stage question is  $3+?=7$ . The next is  $8+?=13$ . This is followed by a whole of 25, then, for the adults, a whole of 42, and a whole of 34. The last three questions are not memorized facts and involve crossing the decade so that interviewees must deal with the whole and the parts as coexisting. Further, the testing rubric requires that children's responses must show evidence of having reached the Abstract Stage, and that adults must show positive evidence of NOT having reached the Abstract Stage.

All the preservice teachers answered the  $P+P=?$  questions correctly. With the  $P+?=W$  questions, the two PSTs of interest answered  $3+?=7$  correctly and without hesitation, showing they were aware of the change in form of the question. Subject 1 then answered "21" for the question " $8+?=13$ "; she gave a sum of the two visible numbers. When the question was reposed, she answered "13", the visible written numeral. For the question " $9+?=25$ ", Subject 1 answered "25."

These are typical answers from Figurative Stage thinkers. At the Figurative Stage, students are only able to deal with the given quantities and, regardless of the form of the question, often take the given quantities as Parts that are to be combined to form the Whole. Alternatively, they give the larger numeral as the answer.

At the question with 42 as the whole, Subject 1 became aware that her answers of 13 and 25 were not correct. After an 11 second pause, she repeated the posed question, which the interviewer affirmed as the correct question. Subject 1 then responded with a guess of "32", then shook her head knowing that 32 was not the answer but not knowing how to find the answer. For the final question,  $8+?=34$ , her minimal finger pressure on the interview table indicated she likely was counting by 1's eight times. Her answer was "27." Instead of "counting down" eight numerals FROM the Whole, she counted eight numerals, STARTING with the Whole, and gave the last-named numeral as her answer.

All of Subject 1's behaviors are found in Figurative Stage children. Subject 1 was unable to answer correctly a  $P+?=W$  question where the Whole was greater than 10. More importantly, she showed no confidence in the correctness of her answers, an important Abstract Stage behavioral response (Steffe & Cobb, 1988).

Subject 2 answered the first two "missing part" questions correctly (Whole is 7 and Whole is 13). The question  $9+?=25$  is the touchstone. Here the subject repeatedly guessed an answer. Her successive responses were 12, 13, 18, 17 and finally 16. The "16" response came after the interviewer had proceeded to the next question.

Subject 2 was using a "guess and check" strategy: keep trying answers until you get the one which gives the correct total when added to the given part in the  $P+?=W$  question. This is a Figurative Stage mechanical procedure that will eventually yield the correct answer. The "guess" and the given Part are added as in a  $P+P=?$  question. There is no sense of part-whole coexistence here. Subject 2's most revealing comment about this problem was, "I have to do it on paper." Pencil and paper mechanical skills

hide her lack of the part-whole concept. Her behaviors, not her final response, show that she is NOT at the Abstract Stage.

When the instructor for these Subjects' math methods class was informed of their interview results, the instructor commented that she was sure there were several more such students in her class of 30, based on their class performance. The percentage result here (13% not-Abstract Stage) is not out of line with that of a small group of volunteers ( $n=11$ ) at another two-year college (36% not-Abstract Stage) (Steinke, 1999), or the 1992 National Adult Literacy Survey, in which 25% of the sampled adult population performed at Level 2 on quantitative literacy tasks and 22% of adults were at Level 1, unable to perform some of the most basic quantitative literacy tasks.

The interviews presented here raise the concern that the conceptual level of some PSTs may lie at the K-2 grade level, well below the mid-elementary-school level studied by most content-knowledge research of PSTs. Those involved in teacher education need to be aware that such students exist, be able to quickly and easily identify such students, and to provide them with targeted instruction in the part-whole concept and other K-2 level concepts. The part-whole concept is a prime underpinning for grasping later math topics. Only with a solid base in their own mathematical thinking can PSTs become effective math teachers (Fennema & Frank, 1992).

## MATHEMATICS TEACHING: FROM FRAMEWORKS TO FLOW

Jennifer S. Thom  
University of Victoria  
jthom@richmond.sd38.bc.ca

Theoretical “foundations”, instructional “units”, conceptual “frameworks”, “networks”, learning “jigsaws”, cognitive “structures”, “scaffolding”, “building” knowledge...and the list goes on. Metaphors. We are constantly reading them, hearing them, using them, and thinking with them. As a result, they often go unnoticed or unquestioned when they are taken to be, simply, figures of speech with which to describe mathematics teaching and learning. Differently, scholars such as Sfard (1997; 1998), Lakoff & Núñez (2000), Bowers (2001), and Abram (1996) interrogate the manners in which metaphors become embodied in our forms of knowing, our actions, and our identities. In keeping with this, the following research sought to: identify the metaphors rooted within my own thinking as a second and third grade mathematics teacher, interrogate the ways they shaped my teaching of elementary school mathematics, and root more ecologically minded metaphors within my classroom practice.

Key metaphors embedded in my taken for granted ways of thinking were: the “mathematics class” as *discrete* entities of teacher, *individual* students, and the *external* environment, “mathematics” as a *connected* yet *fixed* body of knowledge, “teaching” as *facilitating* students’ *movement through an obstacle course*, “learning” as *building* knowledge *structures*, and “curricula” as *assembling jigsaw puzzles*. My enaction of these metaphors in the classroom were evident not only in the written, spoken, and spatial forms given above, but also in temporal and symbolic manners in which I taught graduated, grade specific mathematics programs and how my teaching of concepts progressed always, from “informal, concrete” stages to more “formal, abstract” ones. My teaching focused on enabling the conceptual, procedural, and relational understanding of the autonomous child.

What was revealed by identifying these metaphorical conceptions and the systemic patterns of actions which they engendered, was how my view of classroom mathematics had become “framed” within ways of thinking and teaching which amplified notions of: each child as an “individual”, being “organized”, being “sequential”, and communicating mathematics as “straight-forward”. As well, I had developed conceptual “blind spots”. I was unaware of the mechanistic, linear, and hierarchical manners of thinking that these metaphors embodied. They were not conducive towards engendering ecological, non-linear, dynamically fluid forms of teaching mathematics. The challenge I encountered in realizing the limitations of my metaphors and wanting to enact ecologically coherent forms of teaching was that I could not simply change what I was *doing* in the classroom. Rather, I had to first critically assess, question,

and provoke shifts in my thinking. Below is an excerpt from my journal in which I reflected on my metaphor of curricula as “jigsaw puzzles” in terms of its usefulness for mathematics teaching:

So what of my mathematics curricula as jigsaw puzzles metaphor? The metaphor creates the image of a math curriculum as being a set of pieces... like concepts, skills, domains of mathematics, ...that when given to the students and the pieces are assembled correctly, reveals a coherent picture from its interlocking parts. Okay, yes, this... is a very “tidy” and “systematic” way for a teacher to think about math curricula.... but what this metaphor doesn’t do is reveal the ecological qualities [i.e., an enactive view] which distinguish teaching and learning of math as fluid, co-emergent, and dynamic.... Even if a teacher did manage to design a program that *fit* mathematical topics *together* in a way which *produced* a *complete picture*, the curriculum would remain static. It would still be a set of distinct pieces. (July, 14, 2000)

By reading and working from within an enactive perspective, I developed metaphors that could give rise to forms of mathematical teaching which possessed an open, fluid integrity. The following journal entry details my conceptualization of “geographical maps” for curricula and “paths” for mathematical understanding and learning:

An ecologically coherent metaphor of a mathematics curriculum needs to be one which creates an image of a flexible, dynamic network which evolves as a result of the interactions of the teacher, children, and the environment. A mathematics curriculum might then, [and as Bowers has described] not be thought of as a commoditized “thing”... that which “prescribes” what teachers are to teach and what children are to learn. Gregory Bateson’s “map” metaphor works well in that mathematics curricula can be understood in light of an ecological... perspective. A curriculum envisioned as a map, enables teachers to locate mathematical topics, concepts, and skills that are considered to be important landmarks for the class’ learning. Once these locations are marked out, the teacher can then think about how they are related to one another. This metaphor also expresses the idea that, what cannot be sketched out in advance, are the actual paths which the children will travel...to get to the mathematical locations...or the understandings they will establish when and after they come to these sites. Yes, the map locates mathematical landmarks, but it cannot possibly show the diversity of the landscape (the relational responses of teacher, students, and environment while engaged in mathematical studies)... children’s mathematical paths will likely NOT be linear but instead, spread out in several directions and entail twists, turns and switch-backs. And so, it is only when children and their teacher engage in mathematical interactions that paths of learning come to be. Math curricula

[and learning] imagined in this manner distinguishes them as co-emergent phenomena that are brought into being through children, their teacher, and mathematical settings. (August 2, 2000)

Other metaphors which I conceptualized during the study included: the “mathematics class” to be teacher, students, and the environment as *interacting, interdependent systems*, “mathematics” as a *dynamic, living* entity, as *residue*, and as *source*, “mathematical processes” as *mathematical languaging*, and “mathematics teaching” to be more than me as the teacher but also the material and nonmaterial environment.

These metaphors highlighted for me, ecological notions of non-linearity, dynamic fluidity, co-emergence and complex circularity. They not only created critical shifts in how I thought about mathematics and mathematics teaching, but differences in my teaching also emerged. I created an integrated two year math program as opposed to two, one year programs. I no longer thought of my teaching of mathematics as moving children along sequential curricula but instead, mapped out different mathematical spaces for the class to explore, such as “Who are these things we call numbers?” and “Taking a closer look at snowflakes”. As well, by engaging in mathematics for entire school days instead of 45-60 minute “blocks”, I developed a greater flexibility and understanding for the unpredictability regarding the kinds of mathematics that could and did arise while the children were working.

For instance, as the class studied snowflakes in nature, on video, and in photographs, not only did they lay down learning paths that were diverse and unpredictable, the children collaborated with me in occasioning further investigations based on their learning. These included identifying and reflecting on the number patterns, arrangements that were found to be in multiples of six, and the geometric shapes and structures within snowflakes. The children were also challenged to explore different ways of thinking about and working with their mathematics. Through their poetry, symbolic notation, verbal descriptions, diagrams, and physical models, the mathematics that emerged existed in many forms--forms which were very much *alive*. For example, while making their own Koch snowflake, the children described the mathematics that they were seeing as “growing” patterns of triangles, corners, and sides. The snowflake investigations illustrate how an ecological sensibility in my thinking opened up a dynamic and fluid space for the class to interact with mathematics. Moreover, as the notion of complex circularity was integrated in the way that the class remained working within a particular mathematical space for days, weeks, months, or revisited these spaces, opportunities for recursion to occur in the children’s mathematical understandings were possible. For example, after the children’s initial study of the Koch snowflake, they later returned to it on three other occasions during the school year, reviewing the patterns they saw, and expressing them in descriptive and symbolic forms of addition, multiplication, and division. These revisitings were seen to provoke the children to move back and forth between their previous and present places of know-

ing, thereby giving them time and space to “thicken” and “extend” their mathematical understandings.

### Concluding Thoughts

Researching teaching in the mathematics classroom continues to be a vast, rugged terrain that poses significant challenges for those who explore it while working in the midst of it. In taking an ecological, enactive view, it is important to understand that responsive teaching does not simply mean “moving with the flow” of the classroom or educational system. Teaching responsively involves continually questioning and responding to the ways in which one’s teaching contributes to such a flow. This kind of systemic awareness focuses attention towards understanding the relationships or patterns that connect one’s teaching to the kinds of mathematics and mathematical learning that emerge in the classroom. This study attempts to open a thinking space in which to examine and assess the metaphors which underpin mathematics teaching practices.

**TOOL-MEDIATED PEDAGOGY OF ELEMENTARY TEACHER  
EDUCATION: FROM MATHEMATICS  
ANXIETY TO CONFIDENT TEACHING**

Sergei Abramovich  
State University of New York at Potsdam  
abramovs@potsdam.edu

This presentation focuses on the important role played by cultural tools (commonly referred to as technology in contemporary educational practices) in the development of mathematical and pedagogical content knowledge of pre-service elementary teachers. Particular attention is given to the utilization of various manipulative and computational learning environments, including Unifix® Cubes, Kid Pix Studio® Deluxe, and spreadsheets. The author argues that didactical emphasis on a tool-mediated and open-ended approach to the teaching of mathematics improves traditional pedagogy of memorizing mundane artifacts and computational routines in early grades, provides enjoyable learning experiences for the teachers, and turns one's mathematics anxiety into an enthusiasm towards teaching it.

From a theoretical perspective, a few instructional vignettes featuring the presentation are grounded in well-known action-oriented approaches to the teaching of mathematics to younger children. Furthermore, the vignettes are structured by a context-based and technology-enabled multi-step framework for concept development in a mathematics methods course that stems from the author's early experience in teaching mathematics to gifted children in Russia (Abramovich, 2001). The framework suggests that context itself does not account for a mathematical content. There is evidence, however, that the teachers believe in the robust interplay between the context and the concept and lack the experience of exploring mathematical potential of a particular context. Thus the framework points at the importance of creating situated learning environments that enable the emergence of new concepts from the variation of situated counting questions.

The presentation shows that the use of manipulative and computing technology has a great potential to enhance tool-mediated mathematics pedagogy enabling interactive experimentation with mathematical content and promoting exploratory approach to mathematical concepts. The possibility of interactive experimentation and exploration suggests that the tools of technology can serve as powerful motivational factors in learning mathematics by all students. Included in the presentation comments by the teachers indicate that the appropriate use of cultural tools is conducive to presenting mathematics as meaningful and motivated subject matter that ultimately one would enjoy teaching to younger children.

## THE DEVELOPMENT OF AN INSTRUMENT: MEASURING PRESERVICE TEACHERS' ATTITUDES ABOUT DISCOURSE IN THE MATHEMATICS CLASSROOM [PADM]

|  |   |  |
|--|---|--|
| Tutita M. Casa<br>University of Connecticut<br>tutita.casa@uconn.edu | Thomas C. DeFranco<br>University of Connecticut<br>tom.defranco@uconn.edu | Jean McGivney-Burelle<br>University of Connecticut<br>mcgivney@uconnvm.<br>uconn.edu |
|--|---|--|

This study explores the factors that comprise preservice teachers' (PSTs) attitudes regarding discourse in the K-12 mathematics classroom through the development of a 5-point Likert instrument. Analysis of the PADM ( $N = 277$ ) resulted in three reliable factors: *Promoting Mathematical Reasoning* ( $\alpha_1 = .85$ ), *Examining Complex Mathematical Concepts* ( $\alpha_2 = .81$ ), and *Valuing Students' Mathematical Ideas* ( $\alpha_3 = .85$ ). These results suggest a framework from which mathematics educators can use to prepare prospective teachers to realize recent mathematical reform efforts.

Discourse, or "the [ways] of representing, thinking, talking, agreeing and disagreeing" about mathematics (NCTM, 1991, p. 34) has been a central focus of recent NCTM *Standards* documents (1991, 2000). It allows students to become reflective and critical of their work (NCTM, 2000) while nurturing their development of conceptual mathematical ideas and in-depth knowledge (Brendefur & Frykholm, 2000).

Preservice teachers' mathematics attitudes (particularly in elementary) are generally negative, and most have been exposed to traditional lecture-style mathematics teaching. The combination of these two characteristics presents a situation where prospective teachers are at odds with reform efforts that call for discourse to be used as a pedagogical tool (NCTM, 1991). Since teachers' attitudes predispose them to particular behaviors (Gable & Wolf, 1993) and teaching strategies (Harper & Daane, 1998), we need to investigate PSTs attitudes regarding mathematical discourse. We first must identify the underlying factors contributing to the theory.

This study that was exploratory in nature, developed an instrument that utilized a 5-point Likert scale with the presumption that the items would cluster around NCTM's *Environment*, *Teacher's Role*, and *Tasks*. A principal axis factoring analysis of the pilot, administered in Spring 2001 to a sample of 179 PSTs at a major New England university, derived 6 factors, 3 of which were reliable: *Classroom Environment* ( $\alpha_1 = .80$ ), *Representations of Conceptual Reasoning* ( $\alpha_2 = .73$ ), and *Verbal Communication* ( $\alpha_3 = .77$ ). Items that did not load on a factor were eliminated, those that contained unclear language as indicated by either a low loading or loaded across factors were rewritten, and items that more comprehensively represented the literature and PSTs written responses to questions regarding discourse were added.

The current 26-item version of the instrument was administered in Fall 2001 to a sample of 274 PSTs at the same university. A principal component analysis was

conducted, resulting in a three-component solution detailing more explicit factors than the *Environment*, *Teacher's Role*, and *Task*. Specifically, items clustered around *Valuing Students' Mathematical Ideas* ( $\alpha_1 = .85$ ), *Promoting Mathematical Reasoning* ( $\alpha_2 = .81$ ), and *Examining Complex Mathematical Concepts* ( $\alpha_3 = .85$ ). These factors suggest a framework that can be incorporated into courses preparing PSTs to use mathematical discourse as a pedagogical tool that integrates the three hypothesized factors.

**LEARNING TO TEACH THROUGH MICRO-TEACHING LESSON STUDY**

Maria L. Fernandez  
Florida State University  
fernande@coe.fsu.edu

In recent years, documents such as *Tomorrow's Teachers* (Holmes Group, 1986), *A Nation Prepared: Teachers for the 21st Century* (Carnegie Task Force, 1986) and *What Matters Most: Teaching for America's Future* (NCTAF, 1996) have provided an impetus for increased attention to teacher education programs. These documents indicate that teacher education programs are not preparing teachers adequately to educate future generations of students. In conjunction with these documents and pertaining specifically to mathematics, documents published by the National Council of Teachers of Mathematics [NCTM] (1991, 2000) have provided a vision of mathematics teaching and learning that calls for a revision of mathematics teacher education. Many prospective secondary mathematics teachers continue to lack images of "reformed" teaching, teaching that engages students in experimenting, analyzing, conjecturing, justifying, and making connections. Ball and Cohen (1999) claim that teacher education needs a "fundamentally different content and character than it has now" (p.26). They surmise that much of teachers' learning is based on their own observations of practices from their own learning experiences and their individual observations of teachers in placement schools. For preparing secondary mathematics teachers, we need to engage them in more collaborative tasks, discourse and environments that will help them more systematically develop images of reformed mathematics teaching and the capabilities to reflect on, reason about and engage in change.

For this investigation, a micro-teaching lesson study task was developed to help prospective teachers begin to plan, implement and analyze their own teaching with respect to the *Teaching Standards* (NCTM, 1991). The lesson study task consisted of prospective teachers working in groups of three through two cycles of planning, teaching, and analysis of peer micro-teaching lessons. Working in groups of three, the preservice teachers planned 20 minute lessons to teach to a small group of their peers. The topics for the lessons were selected randomly from a hat; topics included mathematics concepts and relationships that were somewhat familiar to the participants (e.g., types of polyhedra, limit of a function, distance formula) to mathematics that was unfamiliar (e.g., fractals, traceable paths, Euler's Formula). After the planning, each group member was video-taped teaching their lesson to a small group of their peers. After analyzing their own lesson, the participants again in their groups of three analyzed the videotapes of and gave feedback to their two group members. During this time, I, as the course instructor, was reading the lessons and watching the videos to also provide individual and group feedback to the class. Later the groups of three discussed what they had learned from the experience and began a second cycle of the micro-teaching lesson study.

The central question under investigation was 'How does this lesson study influence prospective teachers' development and implementation of reform-oriented teaching and self-analysis of their teaching?' The data collected included group notebooks compiling their lesson plans and reflections, video tapes of their teaching, field observations, and written surveys. Overall, from the first to the second lesson, the prospective teachers' teaching became less teacher centered and incorporated student experimentation, analysis and reasoning to a greater extent. They also enhanced their understanding of the *Professional Teaching Standards*. All eighteen prospective teachers felt the micro-teaching lesson study task was valuable, particularly, the teaching and receiving feedback from others. The majority felt that analyzing others lessons and using the *Professional Teaching Standards* as a framework was of value; however, a few of the prospective teachers felt that watching and analyzing others lessons was not helpful in developing their own knowledge and that using the *Professional Teaching Standards* as a framework to analyze the lessons was somewhat tedious.

## ALLOWING TEACHERS TIME TO LEARN: STAGE ONE

Todd M. Johnson  
Eastern Washington University  
Todd.Johnson@mail.ewu.edu

### The Problem and the Questions

Improving the mathematical preparation of elementary teachers is a crucial element in improving K-8 students' understanding of mathematics. At Eastern Washington University (EWU), pre-service teachers' limited understanding of mathematics is evident in a methods course with two quarters of mathematics as a prerequisite. In a recent section of the methods course when asked to explain which is larger 0.41 or 0.411, 18 of 26 students explained why 0.41 was larger.

Question 1--Will students enroll in a three-quarter sequence of mathematics courses offered as an alternative to the traditional two-quarter sequence?

Question 2—Will the three-quarter sequence of mathematics improve students' retention of mathematical understanding?

### The Experimental Sequence and the Students

The experimental sequence used the same text as the traditional sequence. The additional time in the experimental sequence was used to develop study skills, address students' lack of prerequisite knowledge, have guest speakers, and show videos of K-8 students and classrooms to place learning in context.

The SAT mathematics scores for the 20 students enrolled in the experimental sequence ranged from 330 to 500. Seven of the students had failed the initial course in the traditional sequence. Thirteen of the students had taken remedial mathematics courses at EWU. Five of the students were adult returning students.

### Preliminary Results and Stage Two

The initial analysis of data suggests that students a) will enroll in an additional quarter of mathematics and b) are developing an understanding of mathematics. Twelve of the students enrolled in the experimental sequence answered the following question correctly compared to only 2 of 7 students with a concentration in mathematics enrolled in a methods course.

If  $C$  equals the height of a person in centimeters and  $M$  is the height of a person in meters, write an equation that will give the height of a person in  $M$  meters if the person is  $C$  centimeters tall.

During the 2002-2003 academic year, a) a non-tenure track instructor will teach the experimental sequence and b) in the methods course, the mathematical understanding of students who completed the experimental sequence will be compared to the mathematical understanding of students who completed the traditional sequence.

## THE IMPACT OF EXPERIENCES WITH MATHEMATICS TEXTBOOKS AND CURRICULUM MATERIALS ON PRESERVICE ELEMENTARY TEACHERS' BELIEFS

Gwendolyn M. Lloyd  
Virginia Tech  
lloyd@math.vt.edu

Stephanie L. Behm  
Virginia Tech  
sbehm@vt.edu

Numerous empirical studies over the past decade have indicated that teachers' attempts to enact reform visions in their classrooms are fraught with conceptual and practical challenges, many of which relate to teachers' lack of personal familiarity with reform-oriented instructional practices and representations of mathematics. In light of this situation, it is important for teacher educators to challenge teachers' conceptions of mathematics and pedagogy to promote meaningful, long-term changes in classroom practices.

Our ongoing research project examines the impact of different text materials on the professional development of preservice elementary teachers. In two sections of a *Mathematics for Elementary Teachers* course, different text materials were implemented. In one section [Section A], a widely-used college textbook was implemented (*A Problem-Solving Approach to Mathematics for Elementary School Teachers* by Billstein, Libeskind, & Lott). In the other section [Section B], selected units from reform-oriented middle school curriculum materials were implemented (*Mathematics in Context [MIC]* and *Connected Mathematics Project [CMP]*). The MIC and CMP units were chosen to correspond with the mathematical emphases of the traditional college textbook. Results of mathematical pre- and post-tests indicate that the teachers in the two sections had similar mathematical preparation and gained comparable mathematical knowledge in the course.

Because the text materials are based on different assumptions about mathematics teaching, teachers in the two sections of the course had different learning experiences. For instance, when using the traditional college textbook, teachers are expected to first gain exposure to important information (via the book, the instructor, or both) and then to complete a collection of practice problems for further practice and understanding. In contrast, the reform-oriented middle school units require teachers to engage in investigative activities to develop general rules and concepts *while* they solve problems. Although *mathematically* the two sections of the course were comparable (both sections reached the same mathematical conclusions from their work), *pedagogically* the sections differed in ways that appear to have significantly impacted the teachers' views of teaching and learning, including their views of appropriate curricular materials for teaching and learning. Our poster focuses on differences in these views.

At the beginning of the course, most teachers portrayed a good mathematics textbook as one that contains example problems (solved for students), clear explanations,

practice problems for students to solve, problems representing real-world situations, easy to understand steps for solving problems, and helpful visual aids. Implicit in these beliefs is the notion that students first *learn mathematical material* via clear explanations, examples, and visual displays, and then *practice what they have learned* by solving problems similar to the textbook's examples.

At the end of the semester, teachers in Section A maintained the same chiefly traditional views, and in some cases, *strengthened* their adherence to traditional textbook formats. In contrast, at the end of the semester, teachers in Section B, who worked with middle school materials, appear to have developed several exciting new perspectives including the notion that students can generate ideas and determine mathematical correctness for themselves. This notion, coupled with the suggestion that mathematical understanding includes more than just procedural competence, represents a significant shift from traditional views of mathematics teaching. Section B teachers also identified the idea that teachers can learn about both mathematics and teaching from students' textbooks.

These results, illustrated in greater detail on our poster, suggest that the text materials with which preservice teachers engage impact their conceptions of textbooks as well as their more general conceptions of mathematics teaching and learning. Our results also give rise to numerous questions for further consideration. What differences might we observe in Section A and Section B teachers as they progress through their teacher education programs and early teaching experiences? How might the teachers' classroom practices with mathematics relate to their course experiences as preservice teachers? Investigation of such questions will bring us a deeper sense of what it means for teachers to learn in reform-oriented ways and how such learning much benefit teachers as they interact with children in elementary classrooms.

## ENHANCING STUDENTS' MATHEMATICAL UNDERSTANDING BY DEVELOPING TEACHER CONTENT KNOWLEDGE

Norene Vail Lowery  
University of Houston  
nlowery@uh.edu

Professional development can empower teachers to be better prepared to address mathematics education challenges to enhance student achievement. A cohort of middle school teachers participated in a funded grant program in Texas focusing on strengthening content knowledge, improving instructional strategies, and implementing curricula. Gains were reported in teacher content knowledge, understanding, and skill that may have promoted gains in students' mathematics understanding as reflected on test score results. This discussion highlights the importance of strengthening teachers' mathematical content knowledge (rational numbers concepts and proportionality), strategies, and techniques to promote greater student achievement.

Reform efforts in mathematics education challenge teachers to explore and implement alternative approaches to teaching and learning mathematics. There must be support offered to develop and sustain all teachers. "Teachers of elementary, middle, and high school mathematics need broad and deep knowledge in three fundamental domains: mathematics, mathematics teaching, and students" (National Council of Teachers of Mathematics (NCTM), 1991, p. 191). Through teacher professional development, there are opportunities to enhance student achievement (Loucks-Horsley & Matsumoto, 1999). The NCTM (2000) has identified rational numbers and proportionality as areas needing urgent attention in the middle school. It is crucial that teachers have a solid understanding of the content that they are teaching and have the pedagogical expertise to provide rich learning experiences.

Data were collected through quantitative and qualitative methodologies (pretest/posttests, observations, analysis of student state assessment scores, surveys and questionnaires, and open-ended evaluations). Teachers of grades 6-8 participated in a standards-based, constructivist program that integrated knowledge components (mathematics content, school curriculum, and concept development) with instructional components (student-centered experiences, activity-based learning, use of manipulatives, and technology). Goals were to strengthen teachers' content knowledge in low test performance areas of their students and to implement problem solving strategies through learner-centered activities using manipulatives and technology. Teachers developed confidence in teaching rational numbers and proportionality through cooperative learning, and questioning and assessment strategies. Teachers enhanced personal knowledge of rational numbers and proportionality and began to implement better classroom lessons. Increases in student test scores (ranging from 4.1 to 8.2 percentage points) indicate the teachers may have enhanced student achievement in mathematics by deepening their own conceptual understanding. There must

be opportunities for professional development in content, process, and methodology. It is crucial that a support system in the mathematics learning community be developed along with any efforts to change, alter, and improve the instruction in the classroom (Chapin, 1996). Research in the areas of teacher content knowledge and professional development helps to further a deeper insight into the psychological aspects of teaching and learning mathematics.

## **PRESERVICE TEACHERS' UNDERSTANDING OF WHOLE NUMBER OPERATIONS**

Cheryl Roddick  
San Jose State University  
Roddick@math.sjsu.edu

Julie Sliva  
San Jose State University  
Sliva@math.sjsu.edu

Our primary research goal was to investigate the development of elementary preservice teachers' understanding of arithmetic operations over a semester-long course in number systems, the first of a three-semester mathematics sequence for elementary teachers. Our secondary goal was to use this data to create and implement curricular adaptations. This poster will 1) describe preservice teachers' initial understandings of arithmetic operations; 2) describe changes that were implemented in our mathematics sequence for elementary teachers; and 3) discuss changes in these understandings.

### **Perspective**

Carpenter, Fennema, Franke, Levi and Empson (1999), in their research on cognitively guided instruction (CGI) have developed a framework for analyzing conceptions of addition, subtraction, multiplication, and division. Their work provided a description of the different problem types related to the four arithmetic operations. Specifically, they described in detail the four basic classes of addition and subtraction problems: *Join*, *Separate*, *Part-Part-Whole*, and *Compare*. Carpenter et al. also discussed three problem types for multiplication and division: *Multiplication*, *Measurement Division*, and *Partitive Division*. These problem types encompass the range of grouping and partitioning problems, and each one reflects one of the three quantities that can be unknown. These problem classifications were used in the analysis of responses given in the study that will be discussed in this presentation.

### **Methodology**

The participants in this study are preservice elementary teachers who were enrolled in the first of a three-course sequence in mathematics (Number Systems) designed for elementary teachers. Numerous changes were made to incorporate pedagogical revisions that would positively impact students' understanding of mathematics. Revisions were made according to the new National Council of Teachers of Mathematics Standards (2000); these changes include an increased emphasis on: 1) multiple concrete representations; 2) cooperative learning and mathematical discourse; and 3) technology.

During the course, preservice teachers studied different models used to solve word problems involving whole numbers, and investigated the connections among the operations. Data were collected on these understandings in all of the number systems courses in Fall 2001. An instrument was administered at the beginning and end of the

semester to obtain data on preservice teachers' knowledge of whole number operations. Participants were asked to create two different types of subtraction and division problems, and model their solutions. Six participants were then selected for interviews during the second half of the semester, in order to further investigate understanding of connections among whole number operations.

### Results

Results demonstrated that the dominant models at the beginning of the course were the Separate (Take away) model for subtraction and the Partitive (Sharing) model of division. These models remained dominant throughout the semester, but end-of-semester data revealed that other models were used more frequently than before the course.

Responses from the interviews revealed a broader interpretation of the use of subtraction. Participants were able to discuss the different types of subtraction and division, to varying degrees, as well as model their solutions with some success. What is interesting is that, although none of the students categorized the problems according to the way Carpenter et al. (1999) would, several of them used a consistent and coherent organization scheme, and were able to discuss and defend their decisions.

### Implications

Preservices teachers need to be knowledgeable about the different models related to arithmetic operations, so that they may supply a rich environment for their students in which to investigate such problems. Their future students may also use some of these models in their own efforts to make sense of the mathematics they are learning, and teachers need to be well informed in order to appropriately guide their students.

## MATHEMATICS CURRICULUM REFORM AND THE ROOTED CULTURE OF TEACHING AND LEARNING: THE CASE OF MALAWI

William J. Susuwele-Banda  
Virginia Polytechnic Institute  
and State University  
wsusuwel@vt.eduJesse

L. M. Wilkins  
Virginia Polytechnic Institute  
and State University  
wilkins@vt.edu

The purpose of this study is to describe mathematics education reform in Malawi. Malawi, once a British colony, gained independence in 1964. The country lies east of Zambia and shares borders with Tanzania in the north and Mozambique in the west, south and southwest. Malawi is a landlocked country and covers about 118,484 sq km (46,208.8 sq. miles). The population is approximately 11 million people with a population growth of 3.5%. Total literacy level is approximately 56%. Current primary school enrollment is approximately 3.1 million children and about one third are girls.

Malawi is striving to improve the quality of education through curriculum reform, improvement of teacher education programs, physical infrastructure and strengthening of educational management systems. Due to free primary education, which was introduced in 1994, the education system has experienced an influx of students resulting in high teacher-student ratios, inadequate textbooks, inadequate classrooms and recruitment of untrained teachers. The purpose of this study is to investigate mathematics education reform in Malawi in light of these challenges in addition to a rooted culture of teaching and learning which equates teaching to telling and learning to listening.

Growing evidence suggests that students' learning is more meaningful, and that they feel empowered and more motivated to learn if they are given the opportunity to be active and investigative and take charge of their own learning (e.g., Cobb, Wood, & Yackel, 1991; National Council of Teachers of Mathematics [NCTM], 1989, 2000). Such a vision of learning suggests a different role for the classroom teacher (NCTM, 1989, 1991, 2000; Simon, 1995) and has implications for the preparation of new teachers as well as the ongoing professional development of in-service teachers (Brown & Borko, 1992; Kilpatrick, Swafford, & Findell, 2001). The challenge for mathematics educators in general, and Malawi in particular, is to prepare new teachers that can initiate reform, while at the same time encourage growth and change for in-service teachers. This struggle is not a new one, but is especially challenging in Malawi amidst the many other limitations with which educators must deal.

Based on a descriptive analysis of teacher interviews, observations of school settings, and printed documents, this study provides a snapshot of the present state of mathematics education reform in Malawi. Data depicts efforts being made and challenges being experienced by primary (grades 1-8) school teachers and teacher educa-

tors in Malawi as they try to implement investigative and inquiry-based approaches to the teaching of mathematics (Baroody, 1998; NCTM, 1989, 2000). Data also includes pictures of classrooms, classes in session and school infrastructure. In addition, other materials will depict the evolution of teacher education programs over the past thirty years, both for pre-service and in-service teachers, with particular attention to mathematics education.

Apart from depicting what Malawi is doing to overcome the challenges, this study offers recommendations as well as raises further questions to solicit ideas on how Malawi may forge ahead to improve the quality of mathematics education amidst the challenges being experienced.

## **EXTENDING CLASSROOM BOUNDARIES AND SUPPORTING INSTRUCTIONAL GOALS USING A WEB-BASED COMMUNICATION TOOL**

Patricia Tinto  
Syracuse University  
pptinto@syr.edu

Barbara Shelly  
Syracuse University  
bashelly@sy.edu

The Dialogue application is a web-based communication tool that extends classroom boundaries and supports collaboration among community members. The program's features provide environments where professional dialogue may be modeled and nurtured. The Dialogue contains a hierarchy feature that sustains communication among all members of a learning community within and across courses and over semester and years of a program. Graduates of the teacher preparation program remain in their communities for two years after graduation. The Dialogue application has been most useful to those communities based on the belief that students as a community create a knowledge base for the community and become resources for each other.

The Dialogue Project is the product of education faculty and students working together with a technology research and development group to develop software that responds to the needs of the education community. The focus of the Dialogue project is on both the technology integration issues and the pedagogical issues embedded in the implementation of on-line resource to enhance teaching and learning. It targets issues that arise when producing an application that meets the challenges present in various educational environments. These environments include single courses, learning communities for specific cohorts of students and an entire School of Education program.

The Dialogue application supports multiple aspects of university and schoolwork by providing a variety of workspaces that support in-depth reflection and conversations by students and faculty as well as other members of specific learning communities. The features for this application have emerged from the classrooms and needs of K-16 educators. The metaphor used in the development interface is based on the building of community.

The Dialogue project has three discussion forums called conversations: community wide, small group and one to one. The community-wide conversations are shared with all members of the community. These conversations give each class member the opportunity to share products such as a lesson concept map, a photograph or an original historic document. Small group conversations are among community members but private to the members of the small group community. Small groups have been used to build understandings around observed events, readings, or shared experiences. One-to-one conversations are for those events that are to be shared between a community member and the administrator, or between student and instructor. The one-to-one con-

versation area supports the reflective needs of an educational community. An outcome of both the collaborative and reflective experiences is the creation of a community knowledge base.

Extending this community created knowledge base are resources and a toolbox. Resources are often items such as a syllabus, videos, original documents, and other informative pieces. A community directory holds each member's profile of information to be shared with other members. The toolbox includes evaluation templates, the cumulative record of comments a member has received, as well as the ability to search the community conversations for specific data. Members have the opportunity to create a personal portfolio. A community instructor may create a community portfolio as well as a portfolio of documents for research purposes.

Questions that arise when infusing technology into a course are: what kinds of conversation do instructors want to support; what kinds of conversations and use of resources will help students view an event through more than one perspective or lens; what kinds of conversations and resources will form a basis for students to construct their understanding of the content of the course; and what are the most appropriate technological tools to achieve these goals? This presentation will use data collected during the project to begin to address the above questions.

#### **Note**

The development and the implementation of the Dialogue application is supported in part through Preparing Tomorrow's Teachers to Use Technology (PT3) funding.

## THE IMPORTANCE OF FLEXIBLE MATHEMATICAL AND PEDAGOGICAL CONCEPTIONS FOR SECONDARY TEACHERS

Melvin (Skip) Wilson  
Virginia Tech  
skipw@vt.edu

The poster will focus on secondary teachers' knowledge. Teachers must understand mathematical ideas in different ways than other mathematically trained individuals. For example, it is more important for teachers to understand mathematical concepts in multiple ways. Flexible mathematical understandings not only help teachers to help their students develop deep understandings, flexibility helps teachers understand a variety of possible ways their students might interpret important ideas (e.g., Even & Tirosh, 1995). The poster will provide examples about two theoretical ideas: *mathematical authority* and *pedagogical authority* (Wilson & Lloyd, 2000).

The poster will focus on the mathematical concept of function. To illustrate how college courses might help secondary mathematics teachers develop flexible understandings of important mathematical and pedagogical ideas, the poster will show an activity emphasizing multiple representation of functions. The activity requires teachers to sort collections of functions represented in a variety of ways (Cooney, Brown, Dossey, Schrage, & Wittman, 1996). Cards containing functions will be displayed, as well as descriptions of required sorting tasks and reflections about the pedagogical benefits of sorting activities.

It is important for mathematical ideas to be correct because they make sense and work, not solely because an external authority (such as the textbook or teacher) declares that they are right. This issue exemplifies the importance of reasoning. The poster will show an activity designed to help teachers learn how to share mathematical authority with their students. This example involves teachers writing about and then discussing issues related to historical developments of functions (e.g., Cooney & Wilson, 1992). In addition to communicating the human and changing nature of mathematics, this activity helps teachers understand that most of the common definitions and conventions associated with functions developed out of need (e.g., to solve problems). As with other important mathematical ideas, the definitions and conventions are right because they make sense and work, not because of someone's declaration.

The poster will also illustrate how one high school teacher's flexible understanding of functional relationships contributed to his teaching effectiveness (Lloyd & Wilson, 1998). Although this teacher preferred graphical displays of functions, he was able to attend to some of his students' preferences for tabular representations because he understood functional relationships in multiple ways. It can be argued that everyone should understand functions as relationships between varying quantities, as sets

of ordered pairs, as graphs, as variable expressions, and as tables, but it is even more important for secondary teachers to think flexibly about functions (and other secondary topics).

# **SOME CHALLENGES FOR THE USE OF COMPUTER SIMULATION FOR SOLVING CONDITIONAL PROBABILITY PROBLEMS**

Gabriel Yáñez Canal

Cinvestav-IPN, México; UIS, Bucaramanga, Colombia

gyanez@mail.cinvestav.mx

We present some of the results of an exploratory study with some university students, that besides looking students' intuitive ideas about probability, looking for the spontaneous ideas they have about the frequentist probability and, in particular the difficulties they face solving conditional probability problems using computer simulation. Furthermore, we tried to identify the strategies they used estimating the values of the requested probabilities.

The conceptions and the difficulties that the students have with the conditional probabilities have been widely studied for a long time (Kahneman & Tversky, 1982, Falk, 1982; Gras & Totohasina, 1995; Ojeda, 1994; Sánchez, 1996).

One deeply-rooted idea in the students is that the conditional probability is a measurement of the causal relation that exists between two events, in such a way that the values that the people assign to the conditional probabilities depend on the causal connotation of the conditioning event in relation to conditioned event (Kahneman & Tversky, 1982).

Another deeply-rooted conception in students and related to this causal aspect, is the chronological conception by which is thought that the conditioner event cannot be later in the time than the conditional event. Concretely, Falk (1986) analyzes the following problem:

*Urn Problem.* An urn contains two white balls and two black balls. We shake the urn thoroughly, and blindly draw out two balls, one after the other, without replacement. (i) Suppose we know that the first ball that was drawn was white. What is the probability that the second ball is also white? (ii) Suppose we know that the second ball that was drawn is white. What is the probability that the first ball is also white?

Falk reports that out of the 80 students who responded the first question well, 41 (51.2%) responded  $\frac{1}{2}$  for second, which could be explained by the fact that for the students the first drawing, being causal independent from the result of the second, would have to retain its original probability without considering the result of the second drawing. Falk suggests a physical simulation of the problem, so that the students grasp the idea that the second event can be the conditioning one.

In this same direction is the work of Gras and Totohasina (1995) who ratify the existence of the chronologist and causal conceptions and propose the hypothesis that these conceptions are not correlated, i.e., that they are constructed separately in the

students. In addition, they conjecture, that the used notation of “A given B” can induce a chronological conception as well as “A if B” can be indicative of a causal conception. Both notations make the students think that they deal with a new event. The students who begin the learning of this notion seem develop a certain confusion between the variation of the probability and the variation of the information. This confusion is expressed by thinking that when the information increases the probability increases too, which implies adopting the causal conception of the conditional probability.

Falk (1986) shows how the difficulties in selecting the event to be the conditioning event can lead to misconceptions of conditional probabilities. This is a nice example:

*Chip Problem.* Three chips are in a hat. One is blue on both sides, one is red on both sides, and one is blue on one side and red on the other. We draw one chip blindly and put it on the table as it comes out. It shows a red face up. What is the probability that the hidden side is also red?

Falk relates that the students often mistakenly believe that the probability that the second side is red is  $\frac{1}{2}$ . They argue that there are two possible chips to consider after the first one is shown to have a red side, the RR chip and the RB chip. However, the conditioning event is not the chip, is the side of the chip. Thus, the RR chip has two ways to give us a second side that is red. The probability that the other side is red is thus  $\frac{2}{3}$ .

Confusing the conditional probabilities and the joint probabilities is another one of the common errors among the students when solving problems of conditional probability (Pollatsek and cols. 1987; Ojeda, 1994; Yáñez, 2002).

This confusion takes to Pollatsek and cols. to speculate that, “instead of separate, differentiated of joint and conditional probability, some subjects may have available a concept that is some amalgam of the two.” (p. 269).

From another point of view, Gigerenzer and Hoffrage (1995) reported the result of a theoretical and empirical analysis that allows them to conclude that the Bayesian reasoning in the people improves when the information is given in formats of frequencies, this means, when instead of talking about 5%, it is said that from 100 people, 5 have the disease.

All these exposed difficulties resist to the educative process and the passage of time, as show the researches of Fischbein and Gazit (1984), Fischbein and Schnarch (1997), Lecoutre and Fischbein (1998). For all these reasons, for some time the researchers in these subjects have been proposing that an answer to these difficulties could be to assume the frequentist approach of the probability (Shaughnessy, 1992).

The frequentist approach of the probability responds to an experimental conception of the probability. It is only after having made the experiment several times that the obtained results allow us to make an estimation of the probability of the event at issue. This empirical approach is expressed mathematically in the form:

$$P(A) = \lim_{N \rightarrow \infty} \frac{N_A}{N} \quad (1)$$

where  $N$  is the number of times that the experiment is made and  $N_A$  is the number of times that the experiment was favorable to the event, and thus (1), the limit of the relative frequencies, is the value of the probability of the event  $A$ . Naturally, the use of this approach does not allow to calculate the exact value of the probability but only one estimation that depends on the number of experiments, what in principle adds certain difficulty to the use of this approach in the school. In order to overcome this limitation, the computational simulation allows to generate a great number of repetitions of the experiment and, with graphical aids, to analyze the stability of the relative frequencies and obtain a quite acceptable estimation in most of the cases. However, this idea of “discovering” the trend to the infinite of the relative frequencies is a demanding process that can not support on algorithmic ways, which causes that often the students try to avoid it and resort to strategies that satisfy them and that are not very demanding. The probabilistic process of estimation is the front door to the statistical processes of estimation where the estimations always entail an error what shocks with the mathematical exactitude to which the students are accustomed.

One of the strategies we will show the students use, is *the last generated value* of the relative frequencies, i.e. if they generate 1000 cases, (repetitions of the experiment) the value of the quotient of the number of favorable cases to the event divided between 1000 is the value adopted like estimation of the probability requested.

Besides being a universal problem solver (Batanero 2001, p. 136) the computer simulation has some interesting features for its implementation in the classroom. Some of them are:

- Its close contact with the reality of the random experiments can allow to overcome the people’s misconception about on the chance that oscillates between the idea of a disordered and irregular process and a process where anything can happen with the same likelihood. (Serrano, 1996; Yáñez, 2002).
- It allows to overcome, as Biehler (1991, p. 170) says, the “lack of experience” that the students have about random experiments, providing representations of the real phenomena and increasing the number of repetitions in short time.
- Solving problems by to computer simulation increases the range of problems and realistic situations accessible to students’ activities overcoming the “concept-tool gap” as Biehler says (p. 170), i.e. the gap between the intended generality of the probability concept and the system of operations and tools students actually use.
- Acting as a laboratory, checking the results obtained theoretically. In this sense,

allows an exploration, changing the assumptions of the model, making further experiments, etc.

- The inaccuracy of the produced estimations becomes a trigger to construct a mathematical model that under certain considerations produces exact explanations and results.

With these perspectives, it raises the question about the effects that the computer simulation might have on the understanding of the probabilistic concepts. There are studies that document that even though the simulation as a method for modeling probability problems produces good results, it exists evidence that points out that the random experiences are not enough, neither for improving the probabilistic methods of the students nor for helping to develop the inductive methods. However, it's useful for highlighting their misconceptions and giving the students better explanations about the reality (Zaki, Pluvinae, 1991, Bordier & Bergeron, 1998).

From another point of view, the use of the computer in order to adopt the frequentist approach in probability raises questions about its use that are worthy to study. In this sense, Coutinho (2001) reports some difficulties the students had when several situations were given for building urn models for simulating some probabilistic games. These difficulties are associated with the use of the software, the resistance to use the simulation for solving a problem that can be solved directly by calculation and the difficulty of accepting simulation data that have not been obtained by themselves in order to estimate probabilities.

With these ideas in mind, we are developing a research project to study the effects that produces on the understanding on probability and conditional probability an instruction supported by the use of computer simulation. We are particularly interested in knowing the effects of this instruction on the misunderstanding about probability and conditional probability; in the development of skills to solve problems; in identifying the difficulties that the students have with the use of the computer simulation and knowing the relationship produced between mathematical theory and the reality with the use of the computer simulation.

The search, that has a qualitative character, carrying out an extensive course with the basic subjects of the theory of the probability. Before the course we made an exploratory study to know the difficulties that could be presented with the use of the statistical package Fathom (2000) that demands certain programming to define the attributes that allows to solve problems of conditional probability using simulation. In this exploratory study, besides looking students' intuitive ideas about probability, we look for the spontaneous ideas they have about the frequentist probability and, in particular the difficulties they face solving probability problems using computer simulation. Furthermore, we tried to identify the strategies they used estimating the values of the requested probabilities. Some of the results obtained are the content of this paper (Yáñez, 2002).

### Description of the Students and the Activity

Twelve university engineering students in Mexico City participated in this exploratory study. The activity was carried out in four sessions of three hours each. In the first two sessions besides a diagnostic test for knowing their probabilistic intuition and after a short introduction to the frequentist approach, we started to work with Fathom (Finzer et al., 2000), solving some problems with computer simulation. In the third session the students worked in pairs solved three problems of conditional probability; in the fourth session the students individually solved three problems of conditional probability. The idea was to detect the spontaneous work and conceptions that the students had with respect to simulation and the frequentist probability, and find out the strategies they used in solving problems.

### Presentation and Analysis of the Obtained Results

In the following, we present the solutions given by some of the students to the problems of urn and the chips mentioned in the introduction, and that were proposed to the students in the last session.

#### The Urn Problem

In the diagnostic test, half of the students who participated in the study answered  $\frac{1}{2}$  to the second question showing that they had the chronological conception of the conditional probability, in the sense that they believed the “time axis” prevents an event from being a conditioning event, as had been reported by Falk (1986).

When the students were asked about this problem in the last session to be answered with the aid of Fathom, the answers of some of the students were the following ones:

Carlos, to solve the urn problem simulated the drawings of the two balls with substitution. To answer the first question he produced the graphic in Figure 1.

He wrote:

“From this exercise I can say that the stability is between 0.2 and 0.3 and its frequency is 0.23 with 500 cases. This for question 1, and for question 2 with 500 cases, its stability hardly change, staying between 0.2 and 0.3 and a frequency of 0.274”

Carlos proposes an estimation by intervals that he identifies with the interval of stability of the relative frequencies in the sense that their values from certain moment are included between the given values. In addition, he proposes an estimation that he calls “frequency”, and that corresponds with the last value obtained for the relative frequencies.

However, Carlos’s answer on paper was the following:

- (i) Probability 2<sup>nd</sup> ball is white =  $\frac{1}{3}$  because one ball has been drawn.
- (ii) Probability 1<sup>st</sup> ball was white =  $\frac{1}{3}$  counting all the possible balls and knowing that the second drawn ball was white.

Figure 1. Carlos's graphic for the first problem.

Carlos' analysis and answer on paper and pencil were right, specially in the second question which responds in a similar way to the first one emphasizing the equivalence that exists between the two questions.

As evidence of the transformation that Carlos lived in the course of the activity we showed the answers that he had given when the same problem was asked in the diagnostic test":

- (i)  $P(\text{2nd white ball}) = 1/2$ , i.e. one white and two blacks.
- (ii)  $P(\text{1st white}) = 2/2$ . I say this because it is possible that the two black balls could have been drawn, because the number of balls are the same.

To what extent their new answers are the product of their work with the simulation is an answer that it is still to be unanswered.

Cesar simulates the experiment well and answers both questions correctly. However when he estimates the probability of the second question, which he had not answered in the diagnostic test, with the value 0,33 that he fixes to  $1/3$ , adds: "*I got the same value as the first question but I am not very convinced.*" In spite of his confidence in the simulation process he made, he does not accept the answer because it is against his convictions. Will it be that the single computational simulation is not enough to overcome the misunderstanding of the students and it is necessary to resort to the physical experimentation?

Jose does not simulate the experiment, but as a white ball had already been drawn he simulates the drawing of one second ball of a bag with two black balls and one

white, and to estimate the probability that the ball was white. His programming makes us believe that the students can be thinking not about simulating the random experiment but about making a directed programming to respond the questions asked.

### The Chips Problem

Cesar makes the following programming, where the created attributes appear before the points and the expression that defines them appears after the points. The randomPick function allows to randomly select the characters that appear in the parenthesis.

Bolsa: Randompick("f1","f2","f3")

f1: Randompick("R","R")

f2: RandomPick("A","A")

f3: RandomPick ("R","A")

numf1: if((bolsa = "f1") and (f1 = "R"))  $\begin{cases} 1 \\ 0 \end{cases}$

numf3: if((bolsa = "f3") and (f3 = "R"))  $\begin{cases} 1 \\ 0 \end{cases}$

cantidad: prev(cantidad) + numf1 + numf3

cantf1: prev(cantf1) + numf1

frecuencia:  $\frac{\text{cantf1}}{\text{cantidad}}$

As it is observed, Cesar begins creating an attribute to choose the chip, and although later he defines redundant attributes f1 and f2, his analysis indicates that he assumes that the conditioning event is the sides of the chips.

Rafael identifies the problem with a urn problem where he assimilates each side of chips with a ball that has the same color. His programming was the following:

Bolsa: randomPick (A, A, R, R, A, R)

CaraRoja: if (Bolsa = R)  $\begin{cases} RP(R,R,A,A,A) \\ RP(R,R,R,A,A) \end{cases}$

CaraR: if (CaraRoja = R)  $\begin{cases} 1 \\ 0 \end{cases}$

Sumnacar: prev (Sumnacar) + CaraR

$$\text{RojayRojas: if } ((\text{Bolsa} = R) \text{ and } (\text{CaraRojas} = R)) \begin{cases} 1 \\ 0 \end{cases}$$

$$\text{SumaRyR: prev (SumaRyR) + RojayRojas}$$

$$\text{FrecRyR} = \frac{\text{SumaRyR}}{\text{SumaRyR}}$$

Rafael's design, emphasizes how difficult it can be to define the model of urn equivalent to the problem that is tried to simulate.

The programming made by Alejo shows that he defined the chips as the conditioning event, falling in the mistake related by Falk (1986) and that we previously described in the introduction:

$$\text{Bolsa: RP}(R, A, RA)$$

$$\text{CondR: if } (\text{Bolsa} = R) \begin{cases} 1 \\ 0 \end{cases}$$

$$\text{SumaR: prev (SumaR) + CondR}$$

$$\text{CondRR: if } ((\text{Bolsa} = R) \text{ or } (\text{Bolsa} = RA)) \begin{cases} 1 \\ 0 \end{cases}$$

$$\text{SumRR: prev (SumRR) + CondRR}$$

$$\text{FrecR: } \frac{\text{SumaR}}{\text{SumRR}}$$

His previous conception about the problem prevailing on his programming that does not allow him to observe that when considering the cases where chips R or RA are obtained this includes the cases where the shown face of the second chip was blue.

For solving the problem of the chips Carlos produced a program that allows to calculate the probability of drawing the red side of the chip with two colors. He drew the graph in Figure 2 and wrote: *"I generated 210 cases and with the help of the graph I can say that its stability is between 0.4 and 0.6 and a frequency of 0.46667"*

In the paper he wrote: *"1/2 because one chip is red on both sides and another one is red on one side and blue on the other"*.

Again Carlos, besides talking about stability and the value of frequency calculated with the strategy of the last value, shows that for him there are two different answers: the answer that the computer offers and another one, very different, the one obtains with his analyses in paper and pencil.

*Figure 2.* Carlos's graphic for the chips question of the urn problem.

Luis and Valentín, in the chips problem, as Carlos, estimated the probability of drawing the red side of the chip with different colors. They generated 170 cases and the estimated value was 0.51 using the mode of the results:

"We concluded that the probability of getting the red-red chip is of 0,51 since in the most of the cases the previous result was obtained. In the 7 first cases we obtained a probability of 1 because there is a possibility that same event the chip is red-red."

They made the graph shown in Figure 3.

### Conclusions

From the results obtained, it is seen that the students have difficulties with the modeling of the random experiment and with the programming in the simulation computer language. Confidence in the simulation process may need much more instruction time than the one we used.

Another difficulty deals with the interpretation of the graphs of the relative frequencies for estimating the probabilities. Indeed the necessity to obtain a single value of the probability as a result of a process to the limit (infinite) disturbs the students who resigned themselves to use the last value strategy that identifies the last value of the relative frequencies with the requested probability.

Figure 3. Graphic made by Luis and Valentín in the chips problem.

From the point of view of the programming it also appears a dependency with respect to the questions asked. That means, program according to which it is asked, instead of simulating all the random experiment. It is like they were trying to transfer the theoretical analysis to the simulation computer language. Anyway it is necessary to recognize that the translation of a random experiment to a equivalent urn model not always is evident, which causes that this frequentist approach demands requirements that are not often considered in a traditional education.

It might be that the students make a distinction between a theoretical probability and a simulated one. Some students (Carlos, for example) constructed two types of solutions, one given by the simulation and another one given by a reasoning in pencil and the paper. To what extent one influences on another is a question that still remains open.

When the results in the computer and in the paper were different, they chose the paper answer, maybe because of their lack of confidence in the simulation method and because the estimation by simulation is based on the reading of the trend in a graph in an infinite process.

On the other hand, the problem implied by the estimation of the probability through repetitions of the experiment was not thoroughly accepted by students who had previous experience in the classic probability. So, for some of them, (Luis and Valentín, for example) there are as many probabilities as generated values of the relatives frequencies. For some students, even, the requested probability is the mode of the values of the generated relative frequencies. That means, this problem of the estimation involves problems of convergence not easy at all for the students.

Another thing to mention is the small quantity of cases generated by students showing their belief in “the law of small numbers” and therefore a lack of understanding about the necessity for a large number to achieve the stability of the relative frequencies.

The results of this exploratory study are clear in the sense that when software that demands a certain programming is used, it is not possible to observe effects of the use of the computational simulation on the understanding of the probabilistic concepts without giving a previous and extensive training on the use of the software. We believe that the first approaches to the software must deal with nonrandom situations, for instance, finding the limit of successions defined algebraically. Working with successions is particularly interesting because in addition to allowing the students to develop a “feeling” in the estimation of the limits, they can confront the computational results with the ones obtained by mathematical handlings on the expressions that define the analyzed successions.

Definitively the previous experience with physical devices to represent random experiments becomes a referent to which the student can go in the phase of computational programming. Moreover, it allows him to realize of the necessity of simulating the random experiment more than to give answers to the questions asked.

A direct form to gain confidence with respect to the results of the simulation method is by solving “difficult” problems where the combinatorial that justifies them is not easy to get. Fathom, has even, the option to work with “sampling” which allows to consider more interesting situations, like those that imply the calculation of the expectancy of certain variables.

# **DEVELOPING SECONDARY TEACHERS' STATISTICAL INQUIRY THROUGH IMMERSION IN HIGH-STAKES ACCOUNTABILITY DATA**

Jere Confrey

University of Texas at Austin  
jere@mail.utexas.edu

Katie Makar

University of Texas at Austin  
kmakar@mail.utexas.edu

To support the development of statistical inquiry, teachers must know more than statistical procedures; they must learn to investigate, reason, and argue with statistical concepts and techniques. For mathematics teachers, this is often unfamiliar territory. This study investigates the process of teachers' statistical inquiry and documents its development during a 6-month professional development sequence that immerses teachers in learning statistics while analyzing their students' high-stakes state assessment results. We will report, based on empirical research, how an immersion model in statistics can influence that development.

Increasingly, teachers of mathematics are expected to include uses of data and data analysis in their instruction: Computational power makes the use of data common in today's society and contextual problems stimulate student engagement. At the heart of statistical reasoning is the ability to investigate: to formulate and test hunches, justify conjectures with evidence, and communicate findings, if any, with a convincing argument. Often, an investigation leads to further questions and only tentative answers. In order to support the development of statistical inquiry, teachers must know more than statistical procedures; they must learn to investigate, reason, and argue with statistical concepts and techniques. "The importance of attending to process as well as to content in statistics becomes apparent once we acknowledge that anticipation is at the heart of data analysis" (p. 11, Cobb, 1999). Teachers who expect consistency and predictability will most certainly perpetuate the belief to their pupils that mathematics is about right and wrong answers, faultless algorithms, and certainty. Ambiguity is not usually associated with the mathematical sciences and many traditionally trained teachers see their expertise as resting on facile, quick and accurate recall of a range of mathematical procedures. If students are to become investigators, anticipating and tolerating ambiguity and uncertainty surrounding authentic problems, we must help teachers to develop an investigative mindset. This study investigates the process of teacher inquiry and reasoning and begins to document its development over time. We report how an immersion experience in statistics can influence that development.

## **Theoretical Framework**

Generating inquiry is a skill that requires breaking through a mindset of having to find an answer to every question. Wild and Pfannkuch (1998) argue that a mindset of probing, evaluating, and describing, an awareness of contextual constraints involved, and a balance of curiosity and skepticism are critical to applying statistics. Koedinger

(1998), working in the domain of geometry, argues that the ability to investigate, generate and test “interesting” conjectures, and produce a convincing argument, can in fact be learned by anyone, but “requires self-reflection and extra cognitive resources that come only from practice” (p. 333). Investigation as learners is an area in which teachers have little experience, and for them, the process of change is difficult (Cuban, 1990).

Initial experiences with generating conjectures are frequently stifled or overly simplistic. Student conjectures often focus on one characteristic of the data (Hancock, Kaput, & Goldsmith, 1992; Konold & Higgins, in press). In addition, Cobb (1999) notes the difficulty students have with being autonomous thinkers: “as a consequence of their prior experiences in school, the students assumed that their role was to infer the responses that the teacher had in mind all along rather than to articulate their own interpretations” (p. 7). Trigger questions, used in the quality control industry, can help to stimulate thinking (Wild & Pfannkuch, 1998). The first step in producing trigger questions is learning how to brainstorm ideas without criticism. “Criticism is forbidden in the idea-generation phase, in recognition of the fact that criticism and the urge to censor can stifle the generation of new ideas and erode confidence to suggest them” (p. 336). Motivation to solve problems is also a factor in generating conjectures. Peirce (1923) recognized that inquiry is embedded in a need to resolve doubt. Dewey concurred, and stated the importance of creating a problematic in his statements about inquiry; in investigating, the inquirer needs to feel disequilibrium in order to push ahead to reach a resolution and that an internal cognitive motivator kicks in (Hickman, 1990).

Often, learning in statistics is steeped in rule-based outcomes and statistical formulas that can often discourage inquiry, doing more harm than good (Shaughnessy, 1992). At the elementary and middle school level an early focus on calculations can hinder later statistical thinking; without sufficient conceptual development, the premature use of hypothesis tests at the high school and undergraduate level can aggravate the black and white misuse of the accept-reject dichotomy of statistical tests (Reichardt & Gollob, 1997; Abelson, 1995). Yet content knowledge *is* important for investigation. As study of experts’ approach to ill-structured problems indicated, inquiry “will lead to inadequate solutions unless the individual has and employs substantial knowledge of the domain” (p. 283, Voss & Post, 1988).

### **Research Design & Implementation**

The Systemic Research Collaborative for Education in Mathematics, Science and Technology (SYRCE) at the University of Texas at Austin is conducting a series of studies of methods of research partnership with schools in which a model of systemic reform is investigated. That model (Figure 1) links data on student outcomes to professional development to the building of teacher knowledge and community to the implementation of standards-based, technology-rich curricula and back to student out-

comes. SYRCE is studying how to partner with schools, in order to undertake effective reform, through an approach called implementation research (Confrey, Castro, and Wilhelm, 2000; Confrey, Bell, and Carrejo, 2001). The project was conceived as a mathematical parallel of the Writers Workshop from the National Writing Project, where teachers learn to write rather than to be teachers of writing, and had a set of five related objectives:

1. Strengthen *teacher content knowledge in probability and statistics* by giving them the opportunity to learn statistics well beyond their curriculum, rather than learn how to teach statistics
2. Immerse teachers in *focused investigation and chains of reasoning* about student performance data at an urgent time in a high-stakes accountability environment
3. Build *teacher confidence and facility in using powerful dynamic statistical software (Fathom)*
4. Orient teachers with a *healthy mindset about data and inquiry*: the acceptance of uncertainty when searching for solutions, and the limitations and misuses of statistics and inferential reasoning
5. Provide teachers with an opportunity to be *learners* in an environment that models Standards-based teaching

The long-term conjecture for the project is that when teachers are immersed in content beyond their curriculum in a context they find compelling and useful, this

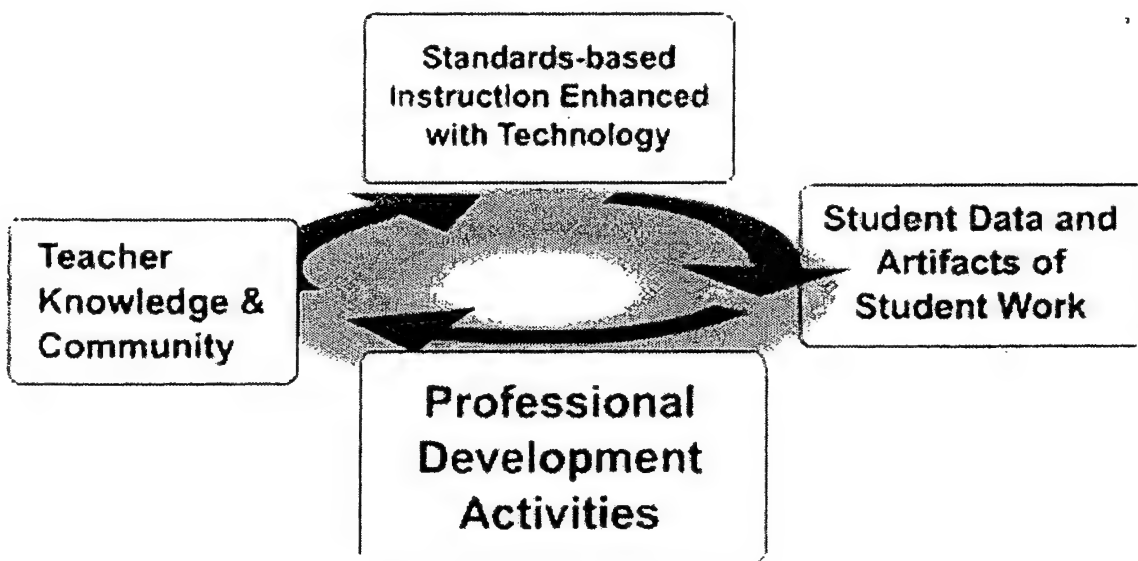

Figure 1. SYRCE model of implementation research in systemic reform.

experience will transfer into improved classroom practice. Specifically, teachers will teach statistics more authentically if their understanding of statistics and how it can be used is developed through their own investigations as statisticians. Another longer-term conjecture is that as a result of these experiences, we should see teachers more willing and able to use technology in their classes, particularly when teaching statistics. In this paper, we concentrate on the fourth objective, describing how teachers' statistical inquiry changes as their understanding of statistics concepts matures in the context of data investigation.

Texas, where the study took place, has a high-stakes accountability system. Students are tested in grades 3-8 and 10 on the Texas Assessment of Academic Skills (TAAS); high school graduation depends on passing in grade 10. Schools and teachers are held accountable for their students' performances. In this climate, urban schools that serve less academically advantaged children are under increased scrutiny and pressure to ensure they do not receive unacceptable ratings. As a result, professional development time is spent focusing on their TAAS results. In general, TAAS results are shared with teachers and schools in the form of summary data and hardcopies of individual student performance. Data are also reported by content and process objectives. Teachers feel that the accountability system creates a context in which they are under the gun and over which they feel very little power. Their stance is reactive, rather than proactive. This context seemed ripe to invite teachers to examine the statistical data as investigators.

Our focus in the project was the mathematics department at our partner school, an urban middle school that feeds into a low-performing high school. The department had five Hispanic women, one African-American woman, and one white male with experience ranging from none to over twenty-five years (median 8 years). Only three of the teachers were certified in secondary mathematics. The demographics of the school are 72% Hispanic, 21% white, and 7% African American. Sixty-two percent of the students are classified as Economically Disadvantaged.

The research conjecture was measured with a pre-post test of statistical content. Additionally, classroom observations were made before teachers began the study providing a baseline of their teaching practice of statistics and mathematics. At the end of the summer institute, teachers presented their findings to their colleagues and an audience of researchers. Clinical interviews at the conclusion of Phase II provided important triangulation of the data collected from the session videos, observations, pre-post tests, and videoed final presentations.

The implementation of the project consists of two phases, which occurred over the course of 6 months. Phase I was carried out from January to May 2001 with two full day and three 2-hour after-school sessions immersing teachers in exploratory data analysis, examination of accountability data, and time for orientation of the dynamic statistical software, *Fathom*. Approximately half of the contact time during the project was spent in front of the computer: learning the software, mirroring hands-on activities,

creating simulations, testing conjectures, and searching for and investigating data. The software that we chose to use, *Fathom*<sup>TM</sup> (Finzer, 2001), is unique in its application as a teaching and inquiry tool. Whereas most statistical software tends to be like a “black box” (data in, answers out), or designed for very specific kinds of tasks, *Fathom* can be used to investigate a broad range of tasks at both an elementary and intermediate level. In addition, many schools in the district had already been purchased *Fathom* (although it was not yet widely used). During sessions, teachers worked to create increasingly more robust formulations and investigations of conjectures about their students’ data while simultaneously building on their statistical thinking, reasoning, and content knowledge. Phase II of the project, a two-week summer institute, provided teachers time and support to further probe specific areas of inquiry of their own choice, examine deeper statistical concepts and tools as they were needed, and present their findings to their colleagues and a group of researchers. Phase I was repeated, by request, as a stand-alone professional development workshop for two intensive days just prior to the beginning of Phase II and included nine secondary math and science teachers from surrounding schools. A high school math teacher and preservice math teacher stayed on for Phase II; only two teachers in the partner school were able and obligated to attend the summer institute (due in part to a change in school leadership).

Typically work sessions began with some limited exploration of a data set as an impetus for continuing with training in the use of the software. A hands-on activity of a statistical concept followed, which was then continued on the computer with the assistance of the newly acquired skill in the software. Teachers were initially introduced to and explored the ideas of central tendency, distribution, variation (particularly as it related to small sample size) and graphical representations of data: boxplots, histograms, dotplots, and scatterplots. During the summer institute, statistical concepts were expanded to include correlation and least squares regression, influential points and outliers, standard deviation and variance, the central limit theorem, confidence intervals, sampling distributions, the null hypothesis, z-scores, and t-tests. We delayed introducing statistical tests until nearly the end of the summer institute, as we feared that the premature use of significance tests would aggravate a mindset of the accept-reject dichotomy of statistical tests (Reichardt & Gollob, 1997; Abelson, 1995). Sampling distributions were used frequently in class problems to imbue a tolerance for variation and to provide a conceptual foundation for confidence intervals, p-values, and t-tests without focusing on formulas and rules. Software instruction was provided on graphs and statistical summaries, importing data, least squares regression, relational graphing, sampling, simulations, hypothesis testing, and more advanced software features (collecting measures, scrambling, and stacking). At an informal level, teachers were able to test simple conjectures within the first few minutes of use with the software. *Fathom*’s ability to easily “drag and drop” variables onto graphs and to be able to link relationships in several graphs made it easy for us to begin using inferential language with teachers from the very beginning.

We pushed to enlarge teachers' view of data to broaden their perspective, encourage more robust conjectures, expect variation and ambiguity, and look for relationships in the data. As a result, every activity we planned worked towards developing a mindset that would allow for a richer experience with the data. Time was regularly used to discuss issues of accountability, reactions to assigned readings, and general issues of data. As the study progressed, increasing time at the end of the day was dedicated to the teachers' own explorations. The study wove the development of teacher knowledge around four strands: statistical reasoning, investigation into student data, the use of the software, and the process of inquiry. This paper focuses on the final strand.

### Results and Discussion

At our first meeting with the teachers, we asked them to come up with conjectures about the data that they might want to investigate – their private “theories” about what they expected to find. Some initial conjectures were framed as topics they wanted to investigate from the data as they struggled for wording questions in the form of a conjecture:

*Brenda:* What about previous scores?

*KM:* So the connection-

*Brenda:* -between previous scores and seventh grade scores.

*KM:* Ok.

*Leesa:* I want to know about the correlation between failing the reading test and failing the math test.

*Larry:* Well, even a conjecture would be: If they fail the language arts, they-

*Leesa and Larry (together):* -fail the math.

Initially, teachers expected that relationships in the data would always be biconditional. For example, if they found that “Students who did well on the TAAS test in grade 7 would tend to do well on the test in grade 8”, they assumed the inverse would also be true: If students did not do well on the TAAS test in grade 7, they would not tend to do well on the TAAS test in grade 8. This conditional conjecturing became useful in breaking through misconceptions teachers had about both data in general and the TAAS exam itself.

When provided the data for their school, the teachers' first reaction was to look up specific students and try to figure out if they could pick out the students who were represented by outliers. At this point, many of their conjectures involved a view of the data focusing on *their* students, *their* classes, or a generic student.

*Larry:* If they score a 3 or better on the writing sample, they should pass the math, I would think.

*Selma:* I have some, purely, they're purely, uh, in my field, ESL. If they came from a non-educational background, and, well—wherever they came from—they're not going to succeed very well here.

Commonly, conjectures focused on questions that could be answered with a single number rather than richer outlook of the data that reflects relationships, trends, or a more holistic perspective. Examples such as "It's been my experience that the seventh grade scores are usually the lowest" reflect this simplistic use of data focusing on a single descriptive sentence. Teachers also struggled with developing an appropriate discourse about statistics. Often they viewed statistical investigations as tasks - wanting explicit instructions on what and how to explore the data - and did not see a need to describe or justify the path they took to reach their findings. When first given open investigation time, they relied on the researchers to give them specific questions to investigate (expecting to find a single, "correct" answer). Just as Cobb (1999) describes the difficulty students have with being autonomous thinkers, at times it was even more challenging for the teachers. Toby, an experienced but fairly traditional high school math teacher found voicing his own ideas uncomfortable. If his thinking was probed in discussions, he assumed he had responded incorrectly. As he ventured out into creating questions, he looked to us for reassurance - Did I say that right? *Can* I ask that? As their tolerance for living with unanswered questions improved, teachers' conjectures were less stifled and began to reflect true curiosity and involvement in the data.

Leesa was more comfortable than most teachers asking her students to create their own questions rather than answer hers. As she first explored data about districts across the state that the Texas Education Agency (2001) posted on the Internet, Leesa wondered out loud if there was a relationship between teacher turnover and salary. An experienced middle school teacher and department head, she found generating inquiries less intimidating than any of our other participants. She kept her notebook close at hand while she investigated and explored new data sets. Ideas that were not written down were soon lost to new questions. Creating an environment, even within oneself, comfortable with unanticipated and unresolved questions is key to building a momentum of 'I wonder's'. Although most of the teachers had taken at least one statistics class, usually many years previously, the experience they remembered in statistics was not about asking questions, it was about answering them, and answering them using just-the-right-combination of a long list of procedures, tests, and monstrous-looking formulas. Once again, re-creating a mindset geared to inquiry was the greatest challenge we encountered.

The professional development workshops followed an immersion model. One of the main objectives of the workshop was to allow teachers to *do* statistics by investigating their own questions. As statistical tools were needed, they were developed through a hands-on activity and/or computer simulation. The problematic was key here - the teachers investigated data, often from their own students, and learned the necessary

statistics, *as it was needed*, to support their investigations. For us, providing a relevant context was critical to getting teachers in the study to look at data with meaning.

In an early session, teachers were shown four pairs of histograms (delMas, Garfield, & Chance, 2001) with no context provided and asked to compare the similarities and differences they saw in each pair (Figure 2). The descriptions teachers gave ranged from bar-to-bar comparisons to reports of means and ranges, to claims of missing data. Many of their descriptions included the shapes of the distributions since they had categorized and named the common distribution shapes in our previous meeting. Overall, the conversation lasted just over 5 minutes. Brenda begins the discussion:

*Brenda:* ...Evidently there's something I'm missing 'cause I keep staring at this ... Um, the first one is just uniform, it's, the frequency stops right, pretty much in the middle. There's nothing going on, I mean ... It just stops. The second one, is it bimodal? It's just going up and down. Uh, there's frequency, and then the zero, I mean there's missing scores. I mean it doesn't start at zero and end at six.

Selma, her partner in this activity, clarified:

*Selma:* Well, she means because zero through one, there's nothing there. ... And five through six there's nothing there. So that's why she was saying some scores seem to be missing.

Following the initial discussion of the pairs of histograms, we added a context to the data and asked teachers to compare the graphs again if each pair represented the quiz scores from two of their classes. Set in a meaningful context, the discussion became richer, and lasted over 40 minutes. Comparisons of the distributions gradually developed into qualitative and more holistic descriptions with emerging observations

Figure 2. Pair of histograms used to compare two groups – with and without context.

(their first) about the spread and “closeness” of the data, theories about how to teach each class, and a discussion of which class would be more challenging to teach. The teachers determined which classes would be more challenging to teach, not based on central tendency, but on something they hadn’t yet articulated.

*Larry:* But you can adjust for that [a difference in central tendency]. ... As long as the class is,

*KM:* The class is what?

*Larry:* More together.

This comparison of the two distributions was the first time one of the teachers had expressed some quality of the spread of the data, beyond just the range. Later, when asked to quantify “more together”, Larry came up with his own rule: “Well, ok, on this one I checked as a matter of fact and it turns out that five-sevenths of the class on each of these is within one score, plus or minus, of the mean.” In later sessions, we continued to provide situations that would help them become aware of the importance of having a robust measure of spread, to look for sources of variation, and to recognize when variation seems extreme. As the expectation for variation in data gradually increased, they slowly lost confidence in descriptions of data solely based on measures of center. As their skepticism increased, they felt more compelled to dig deeper into the data.

As teachers created and investigated conjectures, they were constantly surprised by what they found buried in data that they thought would speak for itself. Statistics is a unique domain in that in doing data analysis, you often come up with more questions than answers. This is rather uncomfortable for novices, especially those trained in mathematics, where answers (correct ones at that!) are expected. In one of our sessions aimed at introducing sampling distributions, each participant was given a die “loaded” with eight small stickers on a single face and asked if they felt the die was fair. Most agreed it was not. They collected data on 30 rolls of their loaded die and decided on how they might argue that the die was not fair. In doing so, they came up with several ideas for creating measures to quantify the discrepancy they saw in their data from what they expected of a fair die: five occurrences of each face of the die. Then they rolled a fair die 30 times to compare the count of each face with that of their “loaded” die and were surprised to find very little perceived difference between the rolls of the loaded and fair dice. There was an air of confusion and disappointment: the results weren’t as they expected, but they were still unconvinced there was no difference between the fair and loaded dies. Following this, we worked with the teachers to create a computer simulation of 100 trials of 30 rolls of a fair die and then graphed a distribution of the measures they had devised. They still found that their “loaded” die was within a comfortable region in the distribution of rolls of the fair die. This provided the opportunity to talk about the null hypothesis and the informal theory behind signifi-

cance testing. Intrigued, most of the participants refused work on anything else until they could create a loaded die simulation and see how loaded it needed to be in order to “detect” a significant difference. Discussions about z-scores and the concept of t-tests ensued. One participant decided the problem was the sample size and rolled his loaded die 60 times to try and detect a difference. What was meant to be a 45-minute activity turned into almost the entire morning with unexpected opportunities to relate difficult statistical concepts to what they were investigating. The disequilibrium they felt in Dewey’s process of inquiry pushed them ahead - beyond what we had anticipated discussing. This investigation became a key turning point in our work with the teachers. For the first time, they experienced control over an investigation. Not only had they built up enough experience with the software that it was now transparent, they felt power in their ability to create and investigate their own questions. This was the first time that they felt enough confidence in their statistical knowledge, mastery of the software, and comfort with experimentation to weave them together into a powerful tool for inquiry. The loaded die activity had also provided an unexpected result: no apparent difference between the loaded and fair dies. The problematic paved the way for them to desire more powerful statistical methods to test conjectures. The very difficult concept of a sampling distribution became a new, powerful tool; z-scores were relevant and an important measure to justify differences between two groups.

At the end of the institute, each participant gave a 30-minute presentation of a conjecture they investigated. Several of the conjectures teachers presented are given below. Although we made it a point to give teachers experience thinking inferentially from the outset, it was much harder than we expected to get teachers to think about providing *statistical* evidence for their conjectures. More often than not, they chose to support their hypotheses with proportional reasoning.

- Practice TAAS tests are not taken as seriously as the real TAAS test and are of limited value, even for those students who need it most (remedial students)
- The schools in our district remediate students at a much higher rate than those in other districts similar in size.
- Test objectives that are problematic at the Exit Level (Grade 10) TAAS are also problematic at lower grades. Furthermore, if students do well on the problem-solving objectives, they are highly likely to pass the overall test
- There is a strong relationship for “typical” (middle 50%) students between the reading and math portions of the TAAS exam.
- There is not a strong relationship between student performance on the TAAS and their performance on the Iowa Test of Basic Skills (ITBS); in addition, the passing level for TAAS is well below grade level on the ITBS. Also, students who do well on ITBS almost certainly pass TAAS, but the converse is not true.

These conjectures reflected a more probabilistic and deeper view of data inquiry than the initial conjectures that focused more on simple answers.

### Conclusions and Implications

Statistical literacy has been heralded as a vital skill for citizens in both the developed and developing world. At a time when misused, high-stakes accountability systems have the potential of retarding the growth of reform-based instruction, it is negligent to ignore their impact and naïve to think they will be short-lived. Rather than ignore what is clearly a system that is here to stay, it is imperative to work with the system to better inform it. This serves two purposes: students will be better served by teachers with stronger content knowledge and support for continuing to implement standards-based instruction; secondly, teachers and administrators will be able to make informed choices based on evaluation of data when implementing programs crucial to student learning. This study is the beginning of a viable model for working with schools to develop their own literacy while submerged in data of their own students. In order to improve statistical literacy in our society, working with schools is an obvious starting place.

As regards our conjecture on immersion, we found that most of the teachers we worked with were reluctant and anxious about undertaking statistical study. They frequently masked their own levels of discomfort with conversation about children's understanding, feeling on safer ground. It became apparent that fundamental statistical concepts were weak, including measures of central tendency as conceptual ideas, recognition of the importance of distribution and variation and simple kinds of issues of display such as how intervals affect shape and what a box plot represents. Nonetheless, we found that as they recognized that they would not be ostracized for a lack of knowledge and as they became more intrigued and competent with the software and statistical concepts, they became more willing to focus on their own learning.

In the arena of inquiry, we believe this is a fruitful area to explore conceptual development. We found that novices start conjecturing in relatively simple ways, seeking single number descriptors, direct comparisons and proportional reasoning. Over time, our teachers were increasingly confident to share their private conjectures and to produce more sophisticated claims and evidence. We believe that when inquiry is developed simultaneously to learning or relearning the content and software tools and in the company of other professionals, the integration of the parts seems to develop more seamlessly. Through an authentic statistical experience in a context that is urgent and compelling to teachers, the research study has shown evidence of change in teachers' understanding of data analysis as a tool for inquiry. In future work, we plan to revise and reimplement the materials and undertake further study of the teachers' inquiry activities. We will also follow them into the classroom to see evidence of impact of their experience on instruction.

## DESCRIBING MIDDLE SCHOOL STUDENTS' ORGANIZATION OF STATISTICAL DATA

Yolanda Johnson  
Illinois State University  
yajohns@ilstu.edu

Pamela Hofbauer  
Illinois State University  
pshofba@ilstu.edu

The purpose of this study was to describe how middle school students physically arrange and organize statistical data. A case-study analysis was used to define and characterize the styles in which students handle, organize, and group statistical data. A series of four statistical tasks (Mooney, Langrall, Hofbauer, & Johnson, 2001) were given to twelve students, 4 from each of grades 6–8, in an interview format. Based on an analysis of the interview data, five categories for students' arrangement strategies emerged: *No Arrangement* (students made no attempt to arrange the data); *Clustered Arrangement* (students sorted the given data in groups with no totals); *Sequential Arrangement* (students listed data in least to greatest order or alphabetical order); *Summative Arrangement* (students provided totals for categories or groups of data); and *Regrouped-Summative Arrangement* (students re-grouped the data into new categories and gave totals). This study implies that students need to be presented with raw, unorganized data sets in addition to organized data sets and ask students to arrange or rearrange data in a meaningful way.

As part of the school curriculum, statistics has been a topic of research for several decades (Jones & Coxford, 1970; National Council of Teachers of Mathematics [NCTM], 2000; Pieters & Kinsella, 1959; Shulte & Smart, 1981). Paulos (1988) mentions that graphical representation is important for every day matters; while Steen (1997) points out that the centerpiece of middle school mathematics includes topics in exploratory data analysis and numerical reasoning. It is important for students to study statistics in the middle school, if not earlier, because the numbers that surround our daily lives are staggering. These numbers can be found on the Internet and in newspapers, television, movie ratings, food labels, consumer reports, and census reports to name a few. Making intellectual decisions in the global society in which we live is a task that every person needs to be able to perform accurately in order to be a better informed citizen and consumer.

Students come to understand the fundamentals of statistical ideas by being engaged in data handling processes such as collecting, organizing, and representing data (NCTM, 2000). According to NCTM, middle school students should begin to compare the effectiveness of various ways of organizing data for analysis or presentation (p. 49). It is also important to remember that in real-life situations, data are not always presented in an organized fashion; in fact, data can be messy. In order for students to make a connection between school and out-of-school mathematics, they should be encouraged to solve problem situations within a meaningful statistical con-

text. However, many of the current middle school mathematics textbooks do not give students the opportunity to handle raw data (e.g., Charles, et al., 2000). Students are typically given organized data within a real-world situation then told to construct a particular graph. While much of the statistics research at the middle school level has looked at how students deal with reducing, representing, and analyzing data (e.g., Curcio, 1987; Mokros & Russell, 1995; Strauss & Bichler, 1988), virtually no research has examined how students organize or reorganize data.

We have taken the view that the first step in building a knowledge base in this area involves describing or characterizing the general strategies that students use when working with data. Thus, this study was exploratory in nature and did not interpret the data through the lens of any particular theoretical perspective. The intent of this study was to describe the strategies middle school students use to organize data.

### **Method**

#### **Participants**

Students in grades six through eight from four mid-western schools formed the population for this study. Twelve students, four from each grade level, were selected for case-study analysis based on levels of performance in mathematics: one high, two middle, and one low.

#### **Instrument**

The interview protocol (Mooney et al., 2001) was comprised of four tasks, each requiring students to arrange data to complete the task. For each task, the students were given the complete data set on paper and the same data with each data value on a separate card. Questions were designed so students could respond orally or by generating tables or graphical representations. At the end of each task, students were given the opportunity to describe an alternate method of reorganizing the data.

A description of each task is provided in Table 1. For each task, students were asked to arrange the data in a suitable format to be presented in the school newspaper. For Task 1, *Shoe Size*, the students were asked to arrange a set of 50 shoe sizes; for Task 2, *Teachers' Pets*, the students were given a set of 39 pets to organize. In Task 3, *Academy Awards*, the students were given the ages of each year's Best Actor and Best Actress Academy Award winners for 30 years and asked to rearrange the data to choose an appropriate headline. Finally, in Task 4, *Classical Music*, the students were given test scores for students in two math classes. The students were asked to reorganize the data to determine if the test-takers who listened to classical music while studying performed better than those who did not. It should be noted that the data for the first two tasks was unorganized. Data for the last two tasks were organized, but potentially needed to be reorganized to complete the tasks.

It said that children who listened to classical music while studying performed better on tests than children who did not listen to classical music while studying. Some of her students planned to listen to classical music while studying for the next math exam. The results of the 80-point test are listed on this table. The students who listened to classical music have an "X" marked next to their name.</p> <p>Your job is to arrange the data to see if students who listened to classical music while studying performed better on the math test than students who did not listen to classical music while studying. The editor of the school newspaper wants you to present the data along with a headline about the comparison</p> |

## Procedure

Using the interview protocol, each student was individually interviewed during a 60-minute session. All interviews were audio taped and all student-generated work was collected. The interviews were transcribed for analysis.

## Data Sources and Analysis

Data sources consisted of the transcribed interviews, students' written work and data displays, researcher field notes, and summaries generated during the analysis. Using a grounded theory approach, we examined students' responses to discern general patterns of arranging data. A double coding procedure (Miles & Huberman, 1994) was used to analyze student responses. We individually coded each student's response based on the type of arrangement the student produced. Then, we compared the coded responses within a category to discern the characteristics of that type of arrangement. Throughout this process differences in categorization and coding were discussed and agreement was negotiated.

## Results

We found that students' arrangement strategies fit into five categories, which will be described in the following paragraphs. The resulting categories were as follows: No Arrangement, Clustered Arrangement, Sequential Arrangement, Summative Arrangement, or Regrouped-Summative Arrangement.

In *No Arrangement*, students made no attempt to arrange the data, leaving it as raw data, or they arranged it inappropriately (see Figure 1). The most obvious way to fit in this category was if no arrangement was provided. Two students (6B, 6C) in the Academy Awards task and two in the Classical Music task (6A, 6B) did not attempt to rearrange the data. The Classical Music task generated the most varied types of responses that we categorized as No Arrangement. Some students dealt with the unequal ends data in an inappropriate manner. Unequal ends are defined here as meaning the data did not include the same number of students in each group. As a result, they forced the data into data pairs, using only 13 of the non-classical music scores to match the 13 test-takers who listened to classical music (7A, 7D). Student 7A chose the top 13 scores of those who did not listen to classical music; whereas student 7D chose the first 13 scores he saw to compare to the test-takers who listened to classical music. The most common example of an inappropriate arrangement was when students found averages that either did not represent the data or did not solve the task. This occurred in the Shoe Size task with four students (6A, 7B, 8A, 8C), in the Academy Awards task with five students (7D, 8A, 8B, 8C, 8D) and in Classical Music task with five students (7B, 8A, 8B, 8C, 8D) who found the average shoe size, average ages of the actors/ actresses, and average test scores, respectively. Three other inappropriate arrangements were presented by students (6D, 7B, and 8C) solving the Classical Music task. Student 6D found the average of the top three scores and lowest

three scores of students who listened and did not listen to classical music and compared those averages. The test in the task was out of 80 possible points, so student 7B figured out what score was a 70% (which he figured, incorrectly, to be 57 out of 80) and found how many students scored above this score. One student (8C) stated that a graph would be inappropriate and that a description of the results would suffice in the school newspaper.

$$415 \div 50 = 8.3 \downarrow 8 \quad 7Bss$$

Average = 8

7 = Mode

2nd Biggest + = Size 9 + 8

Figure 1. No Arrangement.

With *Clustered Arrangement*, students sorted the given data in groups with no totals (see Figure 2). This arrangement appeared only in the Teachers' Pets and Academy Awards tasks. For example, with Teachers' Pets, some students (6B, 6D, 7C, 8D) grouped the pets by the breed of animal or made a new group, but they did not provide a total amount. The students who provided graphical representations (6B and 6D) used a line plot with an 'X' representing each animal. In the Academy Awards task, student 6D placed a '+' beside actors and actresses who were 40 or over and a '-' beside those who were under 40. At the end she saw that she had more '+' for actors than actresses and chose Headline 1. One student (7A) subtracted the actor's age from the actress's each year to see if the difference was more than 10 years (Headline 3), less than 10 years (Headline 2), or negative (Headline 1). Still another student (8B) who provided a Clustered Arrangement looked at the years that the actresses were older to discover this occurred "in about one-third of the years".

In *Sequential Arrangement*, students listed data either in least to greatest or in alphabetical order (see Figure 3). For instance, with Shoe Size, six students (6A, 6B, 6D, 7C, 7D, 8C) decided to list the sizes in order from least to greatest. In the Teachers' Pets task, one student (6C) placed the animals in alphabetical order. For the Academy Awards task, four students (6A, 7C, 7D, and 8C) listed the data in numerical order. In addition, student 7C noticed that there were more shaded ages (actors) close to the

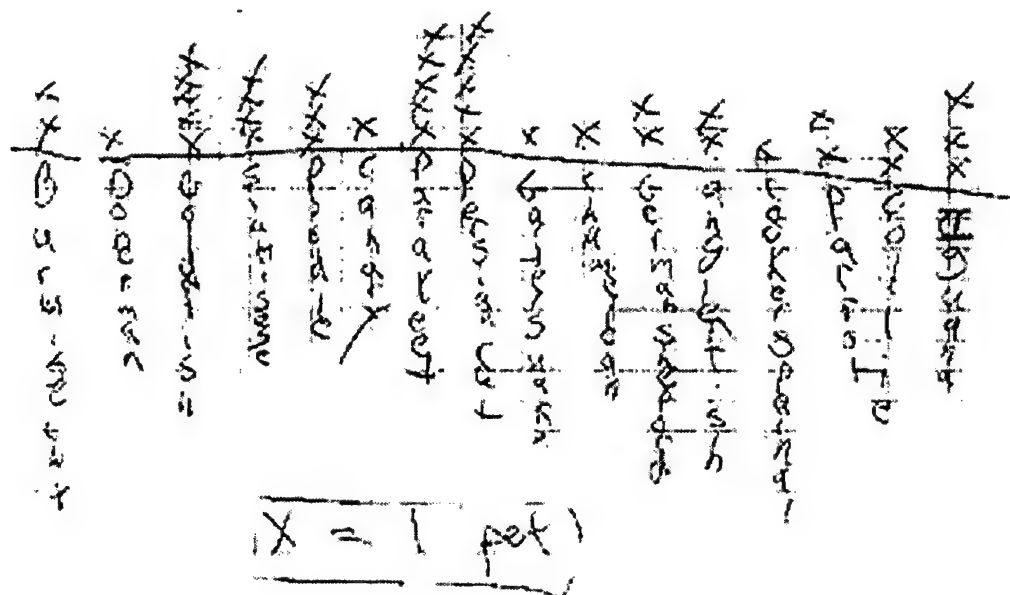

Figure 2. Clustered arrangement.

bottom, where the older ages were and less at the top, where the younger ages were, to reach the conclusion that Headline 1 would fit the data. Student 7D suggested to put the data in a graph with age on one axis and year on another but did not suggest the exact type of graph to represent this data. Four students (6C, 6D, 7C, 8C) arranged the cards in least to greatest order for the Classical Music task and expressed that arrangement of the cards was the best way to present the information in the school newspaper.

With *Summative Arrangement*, students provided totals for categories or groups of data (see Figure 4). For instance, with Teachers' Pets, a student sorted the pets by breed and then provided the total number of each breed in the data set. For the Shoe Size task, in particular, the students mostly arranged the data in a Summative Arrangement (6C, 7A, 7B, 8B, 8D), which included some variation of finding how many students wore certain shoe sizes and representing the data in a bar graph or line plot. One student (6C) placed the animals in alphabetical order, giving a Sequential Arrangement. When asked to provide an alternate arrangement, she joined four other students (7B, 7D, 8A, and 8B), who organized the data in a Summative Arrangement according to the breeds of animals (i.e., Doberman, Cocker Spaniel, German Shepherd, etc.). Two students (8A and 8D) used a Summative Arrangement, comparing age totals between the actors and actresses in the Academy Awards tasks.

Throughout the coding process, we found that some students regrouped the data into new categories and gave totals, which was characteristic of the *Regrouped-Summative Arrangement* (see Figure 5). For example, with Academy Awards, student 7B placed a mark next to winners who were 40 or older and then noted that 10 out of 30

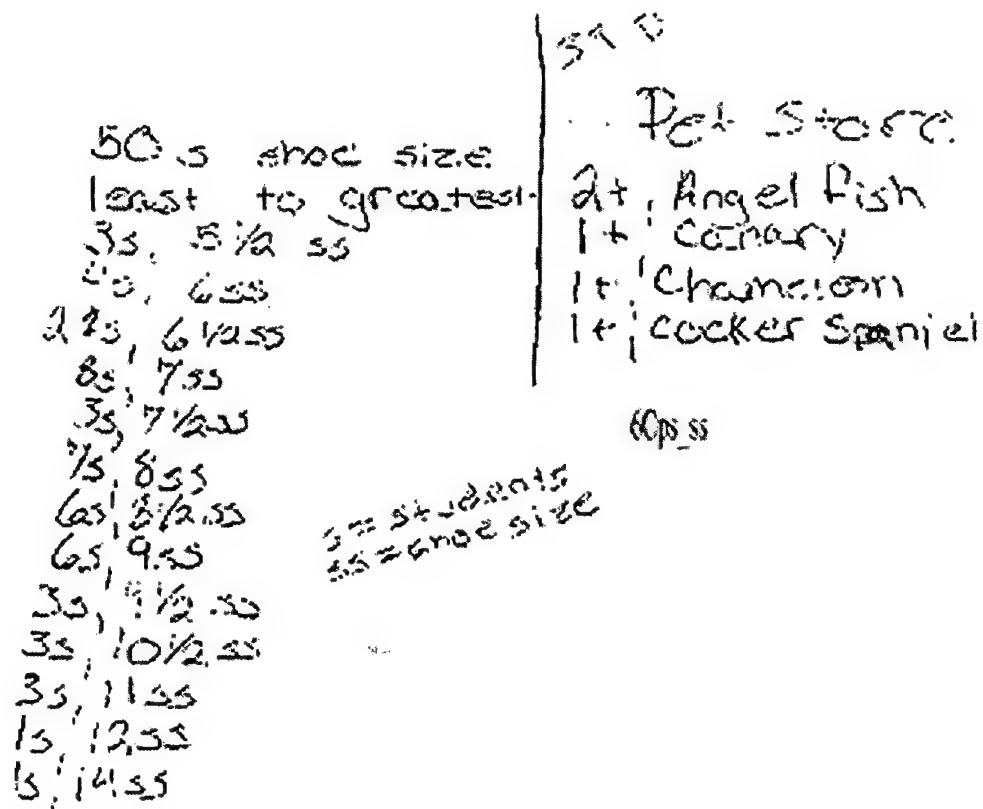

Figure 3. Sequential Arrangement

Figure 4. Summative arrangement.

actresses had marks whereas 19 out of 30 actors had marks leading to a Regrouped-Summative Arrangement. In the Teachers' Pets task, six students (6A, 7A, 7B, 8A, 8B, 8C) grouped the data into categories not given in the data set. For instance, instead of grouping all Dobermans or all Persian cats together, these students formed new groups: Dogs, Cats, Birds, and Reptiles (or Lizards). They went on to sum each new animal group and represent their data in a bar graph, line plot or circle graph.

Table 2 shows how students arranged the data by task, including initial and alternate arrangements. The use of an arrangement was task specific. For Shoe Size, the majority of students' ways of handling the data was split between Sequential and Summative Arrangements. With Teachers' Pets a majority of the students used either the Regrouped-Summative or Summative Arrangement. For the Academy Awards and Classical Music tasks, a majority of the students used No Arrangement as their choice of handling the data. We attribute this to a number of reasons. Both tasks included two data sets presented in an organized table. Some students were satisfied with the presentation and felt no need to rearrange the data while several students expressed their inability to rearrange two data sets within a single task. Still other students found the averages of the data sets, which did not involve reorganizing the original data sets.

Figure 5. Regrouped-summative arrangement.

**Table 2.** Student Arrangements by Task

|  | Shoe Size<br>(Task 1) | Teachers'<br>Pets<br>(Task 2) | Academy<br>Awards<br>(Task 3) | Classical<br>Music<br>(Task 4) |
|--|-----------------------|-------------------------------|-------------------------------|--------------------------------|
| No<br>Arrangement                      | 4<br>27%              | 0<br>0%                       | 7<br>41%                      | 11<br>73%                      |
| Clustered<br>Arrangement               | 0<br>0%               | 4<br>25%                      | 3<br>18%                      | 0<br>0%                        |
| Sequential<br>Arrangement              | 6<br>40%              | 1<br>6%                       | 4<br>24%                      | 4<br>27%                       |
| Summative<br>Arrangement               | 5<br>33%              | 5<br>31%                      | 2<br>12%                      | 0<br>0%                        |
| Regrouped-<br>Summative<br>Arrangement | 0<br>0%               | 6<br>38%                      | 1<br>5%                       | 0<br>0%                        |

*Note.* The percentage values represent the number of students using each arrangement per task. There were a total of 15 Shoe Size, 16 Teacher Pets, 17 Academy Awards, and 15 Classical Music arrangements.

When viewing the results of student arrangements by grade levels (see Table 3), we noticed that the highest percentages of students' arrangements found across all grades levels was No Arrangement. Recall, arrangements in this category include inappropriate arrangements as well as no attempt to handle the data. When the students selected an appropriate arrangement, both the sixth and seventh graders' highest percentage of arrangements was Sequential. The eighth grade students' highest percentage was Summative Arrangement. This grades' lowest percentage was Clustered Arrangement, which was the same for the seventh graders. The lowest arrangement percentage for the sixth graders was Regrouped-Summative.

**Table 2.** Student Arrangements by Grade Level

|  | 6 <sup>th</sup> Grade | 7 <sup>th</sup> Grade | 8 <sup>th</sup> Grade |
|--|-----------------------|-----------------------|-----------------------|
| No<br>Arrangement                      | 7<br>35%              | 5<br>26%              | 10<br>42%             |
| Clustered<br>Arrangement               | 3<br>15%              | 2<br>11%              | 2<br>8%               |
| Sequential<br>Arrangement              | 7<br>35%              | 5<br>26%              | 3<br>13%              |
| Summative<br>Arrangement               | 2<br>10%              | 4<br>21%              | 6<br>24%              |
| Regrouped-<br>Summative<br>Arrangement | 1<br>5%               | 3<br>16%              | 3<br>13%              |

*Note.* The percentage values represent the number of students using each arrangement out of a total of 20 sixth grade, 19 seventh grade, and 24 eighth grade arrangements.

### Discussion

The results of this study show that a majority of the middle school students interviewed were able to reorganize, rename, and sum single sets of unorganized data and give alternate arrangements of data. However, when organized data sets were presented to the students, several were unable to interpret or rearrange the data, possibly due to the fact that they had to handle more than one data set within a single task. Many students manipulated the numbers in the data set(s) and found the average value of the data as opposed to organizing or reorganizing the data. In this study, sixth and seventh graders were more likely than eighth graders to arrange data in an appropriate manner. The eighth grade students mostly tried to find averages for every task or they felt the organized data was in the appropriate format for the school newspaper. When probed to provide a graphical representation, these students were more likely to draw a box-and-whiskers graph.

### Conclusion and Recommendations

Though this research was conducted using a small sample size, it does show that students can handle statistical data when given the opportunity. The sixth grade students we interviewed had recently completed the unit on statistics and probability which would explain the percentage of students who were able to arrange the data appropriately. Retention and additional practice would explain the increase in the percentage for the seventh grade students. However, since eighth grade textbooks generally extend the curriculum to include box-and-whisker, stem and leaf graphs, and line plots, they have an extended repertoire of graphical representations. This additional information with the lack of practice could explain why the eighth grade students had a high percentage of inappropriate graphs. We conclude that students need to be presented with raw, unorganized data sets in addition to organized data sets and asked to arrange or rearrange data in a meaningful way. This practice will allow students' statistical reasoning to evolve and develop which should lead them to effectively organize, analyze, and present data as suggested by NCTM (2000).

## **YOUNG URBAN STUDENTS' CONCEPTIONS OF DATA USES, REPRESENTATION, AND ANALYSIS**

Jill Marshall, Katie Makar, & Sibel Kazak  
University of Texas at Austin  
marshall@mail.utexas.edu

This paper reports preliminary results of an investigation of urban elementary students' thinking on data uses, representation, and interpretation. These results indicate that students generally entered the study with very local, pre-causal views of data, and a predisposition (at least among third and fourth graders) to respond to any data set by simply adding up the numbers. During the course of a five-week mathematics enrichment program, they created their own representations of data that they had gathered, investigated questions they had generated, and explored probability through games based on chance. We saw some students begin to develop a more global view of data and an ability to identify trends in data, while the tendency toward addition diminished. Further, we have identified a natural tendency in some students to create what we have labeled 'bin plots'; such bin plots could form the initial step in a hypothetical learning trajectory beginning with students' native thinking and moving toward standard, conventional representations of data.

Data interpretation is increasingly a focal point in pre-college mathematics curricula. However, urban children may not have sufficient access to Standards-based instruction on this topic. For example, the administrators of an after-school program in an economically disadvantaged urban area in Texas perceived that students in their traditional, skill-based program were not receiving authentic, challenging instruction in mathematics. They negotiated with our research group to develop mathematics enrichment components for the program. One of our objectives in undertaking the task was to investigate elementary students' thinking on data uses, representation, and interpretation. We report our preliminary findings here.

### **Theoretical Framework**

Our framework for this study presupposes that students' understanding of data and their ability to use data in meaningful ways develop over time (Figure 1). Their early understanding, characterized by a local, concrete, and pre-causal (Piaget, 1930/2001) perspective, expands with experience to include global, abstract and logic or data-based thinking. Young students focus on individual cases and are not able to abstract from the specific to the general. Konold and Higgins (in press) document that "younger students tend to make plots that allow them to identify and answer questions about individual data points" (p. 8). Hancock, Kaput, and Goldsmith (1992) concur that students continued to focus on individual cases even after instructional efforts to move them to more group-oriented views of data. Lack of a causal perspective can lead students to focus on appearance and decorative aspects that do not add information as they organize data. Lehrer and Schauble (2000) describe the evolution of

student-generated representations of data and argue that children often do not focus on theoretically important elements. Lacking an understanding of physical causality, young children also predict and explain outcomes based on “morality”: What happens is what should happen, because it is right or to their benefit (Piaget, 1930/2001).

Figure 1. Development of student thinking about data

Our framework also comprises the contention that instruction affects students' thinking on these issues in both positive and negative ways. Schools now incorporate statistics and data analysis into their curriculum as early as Kindergarten (Economopoulos & Russell, 1998). Ideally such instruction would be designed to provide students with a more global perspective, allowing them to use representations of data to compare populations, make generalizations based on subsets, and make predictions based on trends (Friel, Curcio, & Bright, 2001). McClain, Cobb, and Gravemeijer (2000) assert that the ability to identify such “propensities” in the data is central to a “statistical perspective” (p.185). Lehrer and Schauble (2000) argue the importance of meaningful instruction in developing this mindset saying “reasoning about aggregates is necessary for developing and sustaining explanation in many domains, yet this form of reasoning seems to be mastered only over an extended period and depends on thoughtful instructional support and repeated opportunities for practice and use” (p.114).

Many elementary students, however, do not have access to such support and do not have opportunities to develop an understanding of statistics as a natural outcome of interpreting data in a meaningful way as part of an investigation. Statistics instruction is often limited to measures of central tendency and conventional graphing. Shaughnessy (1992) reports that such traditional rule-based instruction in statistics “may have negative effects on students' understanding” (p. 482). Further, some authors argue that an elementary curriculum emphasizing addition and counting to the exclusion of other mathematical concepts may lead students to view these operations as the only legitimate approaches to dealing with numerical data (Confrey & Smith, 1995).

Instruction can also cause students to abandon rich, personal conjectures in favor of more tractable ones. Hancock et al. (1992) report that when using *data modeling* to answer authentic questions, students must be involved in the *creation* as well as the *analysis* of the data: deciding what data to collect and developing organization schemes and systematic methods of measuring and categorizing data. Konold and Higgins (in press) describe the difficulty students had in transforming their original question into one that can be interpreted uniformly and for which appropriate data can be collected.

Recently, attention has focused on construction of representations to help students make sense of graphs and data (Friel et al., 2001; Lehrer & Schauble, 2000). Allowing students to create their own representations and describe their own ideas permits instructors to identify innate tendencies, which can be employed as building blocks in a guided process of constructing knowledge. Bakker (in press) discusses a hypothetical learning trajectory in graphical representation. He highlights that using value bar graphs guides students more intuitively toward the development of conventional plots. In particular, he argues that finding the mean is more intuitive with value bars (than with dots, for example) and identifies the ease with which horizontal value bar graphs can be collapsed vertically to create histograms. Bakker, Friel et al., and Lehrer and Schauble all argue that allowing students to compare and transition between different types of graphs is key to developing their understanding.

### **Methodology/Evidence**

Our approach consisted of developing a Standards-based enrichment unit on data uses, representation and analysis, and implementing the unit in an after-school program. Our study population consisted of 38 students (37 African American and 1 Hispanic, 24 female and 14 male) in grades 3 through 6 in an economically disadvantaged urban area of Texas. These students were a volunteer subset of the students enrolled in the regular after-school program. The data unit was the second in a series of five-week stand-alone units. Students met with instructors four days per week, approximately 45 minutes each day, as a pull-out program from the regular after-school tutoring activities. They were grouped into two classrooms, grades 3-4 (19 students) and grades 5-6 (19 students) at the after-school site. The unit was taught by a team of researchers at the Systemic Research Collaborative for Education in Mathematics, Science and Technology (SYRCE) at the University of Texas at Austin.

During the first three weeks of the data unit, students made representations of data that they had gathered about the weights of their backpacks and derived conclusions from the representations. Students first measured the weights of their own backpacks in groups. Following the approach described in Lehrer and Schauble (2000), we did not prescribe standard forms of data description and display but rather relied on “children’s progressive invention of schemes for inscribing data in the course of an inquiry” (p.115). Students were given paper and markers and asked to show how they

would organize the backpack data either from their group or the entire class. In another activity, students investigated and answered questions they had generated about boomerangs. Later, they used Tinkerplots software (Konold & Miller, 2001) to create graphical representations of the both the backpack and the boomerang data. Finally, students investigated fair games during the last two weeks of the data unit where they obtained data on the outcomes of coin, dice, and spinner games. Students were asked to make predictions about the outcome of the games, and to determine whether the games were fair, that is, whether all players had an equal advantage.

We used both quantitative and qualitative methodologies to investigate our students' thinking. Quantitative assessments included a pre-test at the start of the program, a mid-program post-test at the end of the data unit, and a final post-test at the end of the program. Here we report primarily on the qualitative components. These included analyses of observations and videotapes of classroom interactions, interviews, open-ended responses on the pre and post assessments, and student-produced artifacts, including representations created both by hand and those generated in Tinkerplots. Observations, videos, and interviews were analyzed using standard methods in discourse analysis to describe students' states of understanding and to seek evidence of a growing understanding of data representation and interpretation. Student-produced artifacts were analyzed using project-developed rubrics.

### Results

Our qualitative analyses identified the following tendencies in students' conceptions of data use and representation.

#### **Natural or Moral Law (as opposed to causality) to Explain or Predict Outcomes**

We found children in our study group who clearly fall into Piaget's (1930/2001) pre-causal category. For example, students were given spinners colored one-third red, one-third yellow, and one-third blue. When asked why the pointer had not landed on red as often as blue in a series of trials, Sonny responded that it should land on blue more because "red is a part of the Devil". When students were asked to predict the outcome of a game of chance, they most often predicted that the winner would be *their candidate*, either a personal favorite or the number or color that had won *for them* before (i.e., the result when they themselves had last played the game). For example, a student predicted seven would 'win' (come up most often) in a game where two dice are rolled and the sum added, not because there were more combinations of individual die faces that would add up to seven, but because it had won for her in a previous game.

#### **Focus on Superficial Attributes**

The younger children in the project (especially the girls) tended to focus on aesthetic elements of their representation, spending a great deal of time adding decoration rather than focusing on elements that would assist in communicating their ideas or

answering their questions. Students collected data on the weights of their backpacks and created a representation that would allow them to answer questions about their backpack weights. When Tasha and Hope organized data about backpack weights of students, most of their time was spent decorating. In the representation in Figure 2, Chloe chose a different color for each different bin of tally marks, even though the colors carried no meaning. Even when organizing their data in Tinkerplots, the majority of the third and fourth graders were more interested in creating colorful representations than ones that produced meaningful information.

Figure 2. Chloe's representation of her group's backpack weights. Each letter represents a child in the group.

### Tendency to Focus on Individual Cases

Confirming that young children focus on individual data cases rather than group characteristics (Bakker, 2001; Konold & Higgins, in press), our students sometimes used an individual case to answer a question about an entire group. For example, our students were quick to identify the extreme cases when asked to make true statements about the weights of their backpacks, but not to identify global trends in the data. The transcript below records a typical response.

RN: If this was the data that we collected, what could you tell me about the weight of the backpacks for this group of people?

Cherise: The highest one was this one (pointing to bar with highest value).

RN: That's Kendra, and hers was 20 pounds.

Cherise: And the lowest one was Sonny.

This tendency persisted for some students, as evidenced by their responses on the post-test at the end of the unit, in which they were shown the value bar graph in Figure 3 and asked, based on the graph, who reads more, boys or girls. This graph was generated using Tinkerplots, and the length of each bar represents the number of books read by an individual student. The bars in the graph that students saw were color-coded, yellow for girls and pink for boys. In the reproduction here, the girls are the lighter gray and the boys are the darker gray.

Five out of 30 students answered based on a single student who had read the most books (boys read more because "Roberto read more books than anybody" or "a boy read 14 books"), ignoring the general trend. On the other hand, eight students responded that girls read more, giving reasons like "more girls are at the top", "more girls higher up."

Figure 3. Tinkerplots representation of books read.

### Personal Identification with Data Representations

Even as young children create models that resemble their referents (Lehrer & Schauble, 2000), we found that children continued to identify classmates with data points long after representations became more abstract. For example, when students saw the weights of their backpacks plotted in Tinkerplots, they took note that the value bar corresponding to Leon, an African-American boy with the lightest backpack, was

white. Even later, when students were creating their own representations using Tinkerplots, one student pointed to the white segment in a pie chart that he had created to represent the backpack data and turned to his neighbor and exclaimed, "Look, who is this? Leon is white!"

### **Preference for "Bin Plots"**

Our fifth- and sixth-grade students showed a clear preference for value bar graphs, as opposed to dot plot or frequency representations such as histograms when they were instructed to create a chart or graph. This is very likely due to their school curriculum, which includes bar graphs at this grade level, and to the tendency of teachers to emphasize correct procedures for constructing bar graphs over opportunities for construction of data inscriptions of the students' own creation. Our study also confirms Bakker's (in press) work identifying student preference for value bar graphs over dot plots when landscape-type statistical tools such as Tinkerplots permit them a choice of representation. We see, however, a more primitive stage of development in a preference for "bin plots" among our third and fourth graders. These are data representations in which the number of markers within a bin represents the value of one case, in the same way that the length of the bar does in a value bar graph. An example is Chloe's representation of her group's backpack weights, shown in Figure 2. Here she uses individual pound markers, arranged in rows and columns within a separate bin, as specifiers to represent the weight of each student's backpack.

### **"Addition Syndrome"**

When given open opportunities to respond to data, our students often reverted to adding up the numbers, thus reducing the distribution to a single (and in many cases meaningless) number. When asked to organize data on backpack weights for their groups, for example, many students responded by adding the totals rather than comparing distributions. Note that, in Figure 2, Chloe has added up the individual weights and presents the sum (55) as part of her representation. The tendency was extremely common among third and fourth graders, the majority of whom added the weights of the backpacks as part or all of their representation of the data. In another activity, students were asked what they could say based on a value bar graph showing backpack weights colored differently for girls and boys in their class. Note that two of the three students whose responses are transcribed here made a response based on addition, while only one commented on a trend that is visible in the data.

Jonah: The girls altogether weigh 53 pounds. And the boys weigh 30 pounds.

Marcus: The blue is the, is kind of to the lighter side and the girls are more... The girls weigh more than the boys.

Diana: I think the girls weigh more than the boys because there is one young boy that weighs 19 pounds and there's another [girl] that

weighs 10 pounds and if you like add all the girls, all the three girls' pounds, for their backpacks together then it comes to the biggest number and if you add the two boys' backpacks together then it comes to a smallest number.

We saw this tendency diminish as the unit progressed. When asked to make a true statement based on the graph shown in Figure 3, taken from the post-test at the end of the unit, no student responded by adding up the total number of books read. On a second post-test at the end of the academic year, only one student out of 11 who took the test added up the data in response to a question about whether a third grader or a fourth grader was likely to sell the most candy based on data from a graph.

### **Loss of Confidence in Self-generated Conjectures**

Our students tended to modify their originally rich, meaningful questions into ones for which data could be collected and analyzed. Questions that students wanted to answer at the beginning of an investigation showed a great deal of interest in the flight of boomerangs. For example, students were interested in finding out both how far each of two different styles of boomerang flew and how close each one landed to its thrower. However, after collecting and representing their data, most students found that they had not recorded the data needed to answer their questions and found themselves answering questions about the data, rather than the boomerangs, or answering questions about the boomerangs that did not at all resemble the questions originally intended.

### **Discussion**

Our results indicate that, in general, our students entered the study with a local, concrete and pre-causal perspective in thinking about data. The tendency to respond to a general question about a data set based on an individual point is a sign that students had not yet developed a global perspective. They did not, in general, "think about data sets as entities that have properties in their own right rather than as collections of points" (McClain et al., 2000, p.175), which is a desired outcome of instruction in statistics. Their focus on decorative aspects of data representation indicates that they did not see data primarily as a source of information, from which generalizations could be drawn and predictions could be made. This attitude that data are not useful in creating logical inferences and explaining outcomes is a sign of pre-causal thinking. Children, for example, might believe that boomerangs fly well simply because they want them to, or because "that's just the way it is," rather than because of their shape or some other characteristic whose relation to flying well could be measured. Such children may not see any reason to seek out trends in the data. For them, the salient feature of the graph may be its appearance, making it more likely that they will spend their time predominantly on decorating the graph. In the same manner, the expectation that the outcome of a game was likely to be similar to one that they had experienced person-

ally, or to be what they wanted it to be, is also a sign of pre-causal thinking. Adults might expect natural variation in outcomes; children typically believe that any given outcome “admits of justification or of motivation as everything in nature has been willed” (Piaget, 1930/2000, p. 275).

Likewise, our students’ personal identification with data points is evidence of concrete thinking. To them, the data point representing Leon’s backpack was about *Leon*, and not an abstract element of a set of data from which generalizations could be made. Hancock et al. (1992) report a similar tendency in the children they worked with.

It could also be argued that the tendency to associate the data with its referent represents an awareness of *context*, which is considered a key component of statistical thinking and also a desirable outcome of instruction in statistics. For example, our students were shown data representing the amounts of candy sold by students in one third-grade class and one fourth-grade class, clearly showing that in general the fourth graders sold more candy. Students were told that another third-grade and another fourth-grade class sold candy, and asked whether they would guess that the student who sold the most out of those two classes would be probably in the third grade, or probably be in the fourth grade. One of the fourth graders in our study based her response on her personal knowledge of third and fourth graders (A fourth grader would sell more because fourth graders have the “props [signs, displays] and ways” to sell more), rather than on an argument from the data. Hancock et al. describe this as “the dominance of personal knowledge” (p.387) and argue that it limits a student’s inclination to use data to answer questions. It is possible, for example, that had the data on candy selling indicated that, in general, third graders sold more candy, our fourth grader would have trusted her personal knowledge and discounted the data as not representative. On the other hand, a more generalized awareness of context might serve to make students aware of cases in which a data sample might actually *not* be representative, limiting its effectiveness in extrapolating a general answer.

In the course of our work, we found evidence that instruction can affect students’ thinking in both positive and negative ways. A case in point of a negative effect is the “addition syndrome” we observed among third and fourth graders. We assert that this tendency to reduce all data sets to a single number by adding up the values, regardless of whether the sum had any meaning with regard to the questions under consideration, is the result of an elementary curriculum with a strong focus on addition, to the exclusion of other ways of looking at data. Likewise, by exhorting our students to refine their original questions to ones whose answers could be determined based on data readily measured within the time allotted and with the equipment available, we may have led them to believe that, in general, real questions do not yield to data-based analysis, and reinforced their teleological perspective. The answer to “Why is a boomerang made of this foam material?” might just as well be “Because that’s just the way it is” if we give students the impression that there is no way to find an answer to authentic questions through investigation.

On the other hand, we believe that our students did make some progress toward a more global perspective on data as a result of the program of instruction they experienced. By the end of the unit, while some students continued to focus on outlier points, others had begun to base responses on group propensities, as seen in their responses to the post-test question. We assert that this change was due to their experiences with creating and discussing data representations, in particular their experiences with Tinkerplots. It is much easier to see at a glance that “more girls are at the top” from a Tinkerplots graph than from a list, as can be seen in Figure 3. Students provided justification such as “because there is more yellow and that stands for girls” in deriving a result from the data in Figure 3. This clearly indicates a visual assessment of the data, facilitated by the color-coding made possible by Tinkerplots.

Tinkerplots may also have helped to curb the ‘addition syndrome’ in our third and fourth graders. When these students were first introduced to Tinkerplots, they were disappointed that it would not allow them to add up the data values they had entered. In fact one student went so far as to suggest that we needed to access other software (“You could go to ‘addition.com’”) to make this possible. However, as our students were able to discover other ways of organizing and analyzing data with Tinkerplots, they seemed to think less in terms of addition as a response to data, as seen in their post-test responses. These exploratory results, if confirmed, bode well for the possibility that elementary students can develop a statistical perspective through investigation-based instruction using software that allows them to display and manipulate data in a variety of ways with ease.

Finally, we have identified a native tendency among students, the bin plot, which could serve as a building block for the construction of understanding of standard forms of representation. According to Friel et al. (2001), “Unlike plans, maps, or geometric drawings that use spatial characteristics (e.g., shape or distance) to represent spatial relations, graphs use spatial characteristics (e.g., height or length) to represent quantity” (p.126). By this definition, a bin plot qualifies as a primitive form of graph, in that the *area* of the array of specifiers within each bin corresponds to a quantity (in Figure 2, the weight of an individual backpack), but the discrete specifiers are still retained. In that sense, a bin plot represents a transitional state between an iconic representation in which one “sees” 12 individual tally marks to represent 12 pounds, and a more standardized value bar graph, in which the length of the bar represents the quantity.

Note that these bin plots invert the standard “line plot” construction (see Figure 1 from Friel et al., 2001, p.127). In Chloe’s bin plot, the horizontal dimension is demarcated into bins, which represent individual students’ backpacks (Figure 2), while the markers represent units of a quantity (pounds). Conversely, in a traditional line plot, horizontal positions along the line are labeled to represent units of a quantity (pounds, for example), while individual cases show up as markers (x’s, for example) stacked in the vertical direction. As such, one might argue that allowing students to focus on

bin plots might impede progress toward understanding of representations based on frequency (histograms). However, it is easy to see how a bin plot that was constructed using graphing software with sufficient flexibility could be reshaped so that the array in each bin had the same width or the same length, allowing a smooth transition to a value bar graph. As mentioned above, Bakker (in press) presents a similar natural transition that allows line plots or stacked dot plots (precursors of histograms) to be created in the collapse of horizontal value bar graphs. Thus we have a possible learning trajectory beginning with iconic representations, then moving to bin plots, value bar graphs, frequency-based line plots and finally standard histograms. With appropriate software, these transitions could be accomplished through a series of visible manipulations of the data, which could serve to heighten understanding.

### **Conclusions and Implications**

Our results indicate a strong need for urban elementary students to have ample opportunities to carry out the full spectrum of an investigation: making a conjecture, obtaining data, organizing and creating representations of data, and synthesizing the propensities of the data they have gathered to reach conclusions. Our results imply that urban elementary students will benefit from viewing and representing data in a variety of forms, especially those that exploit their native tendencies. Allowing students to create representations and ways to quantify data that make sense to them will counter the tendency to simply add up numbers, or produce standard plots that hold no meaning. This implies that software and other tools that allow students maximum flexibility in representing data should be developed. If students' initial tendency is to organize data into bin plots, then it is important that software allow them to enter data without regard to order or frequency, and to display values in terms of discrete units (pound markers) rather than simply as the length of a bar or a position in Cartesian coordinates. Further, such software should facilitate movement through a hypothetical learning trajectory, for example, by readily converting bin plots to value bars, and then collapsing value bars to a standard histogram plot. Clearly further study is called for to verify this conceptual path and develop and assess curricular sequences to exploit it.

Understanding how urban children represent, analyze, and use data is a comparatively new area of study. Further research is needed on all aspects, from cognition to classroom implementation. Our work in an urban after-school program showed that such strategies can be successful. However, keeping in mind that teachers tend to emphasize correct procedures for producing graphs rather than encouraging students to generate their own representations and allowing those representations to evolve over the course of inquiry (Lehrer & Schauble, 2000), implementation research in actual urban classrooms will be necessary to determine the conditions and supports necessary for working teachers to adapt these strategies.

# STUDENTS' SCHEME-BASED CONCEPTIONS OF SAMPLING AND ITS RELATIONSHIP TO STATISTICAL INFERENCE

Luis Saldanha  
Vanderbilt University  
luis.a.saldanha@vanderbilt.edu

Patrick Thompson  
Vanderbilt University  
pat.thompson@vanderbilt.edu

We distinguish two conceptions of sample and sampling that emerged in the context of a teaching experiment conducted in a high school statistics class. In one conception “sample as a quasi-proportional, small-scale version of the population” is the encompassing image. This conception entails images of repeating the sampling process and an image of variability among its outcomes that supports reasoning about distributions. In contrast, a sample may be viewed simply as “a subset of a population”- an encompassing image devoid of repeated sampling, and of ideas of variability that extend to distribution. We argue that the former conception is a powerful one to target for instruction.

## Background

On the basis of empirical evidence Kahneman and Tversky (1972) hypothesized that people often base judgments of the probability that a sample will occur on the degree to which they think the sample “(i) is similar in essential characteristics to its parent population; and (ii) reflects the salient features of the process by which it is generated” (p. 430). This hypothesis suggests that Kahneman and Tversky’s subjects focused their attention on *individual* samples. In later research, Kahneman and Tversky (1982) conjectured that people, indeed, tend to take a *singular* rather than a *distributional* perspective when making judgments under uncertainty. In the former, one focuses on the causal system that produced the particular outcome and assesses probabilities “by the propensities of the particular case at hand” (p. 517). In contrast, the distributional perspective relates the case at hand to a sampling schema and views an individual case as “an instance of a class of similar cases, for which relative frequencies of outcomes are known or can be estimated” (p. 518).

Konold (1989) found strong empirical support for Kahneman and Tversky’s (1982) conjecture. He presented compelling evidence that people, when asked questions that are ostensibly about probability, instead think they are being asked to predict *with certainty* the outcome of an *individual* trial of an experiment. Konold characterized this orientation, which he referred to as the *outcome approach*, as entailing a tendency to base predictions of uncertain outcomes on causal explanations instead of on information obtained from repeating an experiment.

Sedlmeier and Gigerenzer (1997) analyzed several decades of research on understanding the effects of sample size in statistical prediction. They argued compellingly that subjects across a diverse spectrum of studies who incorrectly answered tasks

involving a distribution of sample statistics may have interpreted task situations and questions as being about individual samples.

Recent instructional studies (delMas, Garfield, & Chance, 1999; Sedlmeier, 1999) indicated that engagement in carefully designed instructional activities using computer simulations of drawing many samples can help orient students' attention to collections of sample statistics when making judgments involving samples. However, analyses in these studies did not focus on characterizing students' evolving conceptions and imagery in relation to their engagement in instruction.

Despite the centrality of variability in statistics, students' understanding of sampling variability and our comprehension of variability's role as a central organizing idea in statistics instruction has received little research attention (Shaughnessy, Watson, Moritz, & Reading, 1999). Rubin, Bruce, and Tenney (1991) proposed that a coherent understanding of sampling and inference entails integrating ideas of sample representativeness and sampling variability to reason about distributions. Images of the re-sampling process, however, were not at the foreground of their conceptual analysis. Other conceptual analyses of sampling (Schwartz, Goldman, Vye, & Barron, 1998; Watson & Moritz, 2000) characterized the relationship between population and a randomly selected subset of it in a way that did not entail images of the repeatability of the sampling process nor of the variability that we can expect among sample outcomes.

In sum, substantial evidence from research on understanding samples and sampling suggests that students tend to focus on individual samples and statistical summaries of them instead of on how collections of sample statistics are distributed. Furthermore, students may tend to predict a sample's outcome on the basis of causal analyses instead of statistical patterns in a collection of sample outcomes. These orientations are problematic for learning statistical inference because they disable students from considering the relative unusualness of a sampling process' outcome. Finally, sampling has not been characterized in the literature as an interrelated scheme of ideas entailing repeated random selection, variability, and distribution.

### **Purpose and Methods**

This study investigated the development of students' thinking as they participated in instruction designed to support their conceiving sampling as a scheme of interrelated ideas including repeated random selection, variability among sample statistics, and distribution.

Twenty-seven 11<sup>th</sup>- and 12<sup>th</sup>-grade students, enrolled in a non-AP semester-long statistics course, participated in a 9-session whole-class teaching experiment (TE) addressing ideas of sample, sampling distributions, and margins of error. Our aim was to develop epistemological analyses of these ideas (von Glasersfeld, 1995; Steffe & Thompson, 2000; Thompson & Saldanha, 2000) – ways of thinking about them that

are schematic, imagistic, and dynamic – and hypotheses about their development in relation to students' engagement in classroom instruction.

Three research team members were present in the classroom during all lessons: one author designed and conducted the instruction; the other author observed the instructional sessions and took field notes; a third member operated the video cameras. Students' understandings were investigated in three ways: by tracing their participation in classroom discussions (all instruction was videotaped), by examining their written work, and by conducting post-experiment individual interviews.

Instruction stressed two overarching and related themes: 1) the random selection process can be repeated, and 2) judgments about sampling outcomes can be made on the basis of relative frequency patterns that emerge in collections of outcomes of similar samples.<sup>1</sup> These themes were intended to support students' developing a distributional interpretation of sampling and likelihood. Though an a priori outline of the intended teaching and learning trajectories (Simon, 1995) guided the progress of the teaching experiment, the research team made on-line adjustments to instruction according to what they perceived as important issues that arose for students in each session.

The teaching experiment unfolded in three interrelated phases: it began with directed discussions centered on news reports that mentioned data about sampled populations and news reports about populations per se (raising the issue of sampling variability). The experiment then progressed to questions of "what fraction of the time would you expect results like these?" This entailed having students employ, describe the operation of, and explain the results of computer simulations of taking large numbers of samples from various populations with known parameters (see Figure 1).

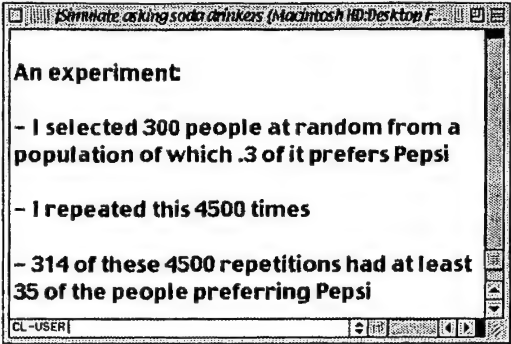

[insert Figure 1 here]

The experiment ended by examining simulation results systematically, with the aim that students see that distributions of sample proportions are largely unaffected by underlying population proportions (see Figure 2), but are affected in important ways by sample size.

### Results and Discussion

In this report we move toward elaborating an important distinction between two conceptions of samples and sampling that emerged in the teaching experiment. Our analyses revealed that some students – generally those who performed better on the instructional activities and those who were able to hold coherent discourse about the mathematical ideas highlighted in instruction – had developed a multi-tiered scheme of conceptual operations centered around the images of repeatedly sampling from a population, recording a statistic, and tracking the accumulation of statistics as they distribute themselves along a range of possibilities. These images and operations were tightly aligned with those promoted in classroom instructional tasks and discussions.

*Figure 1.* Part of an instructional activity designed to help students make sense of computer simulations of drawing many random samples from a population. Simulation input (left) and output (right) windows were displayed in the classroom and the instructor posed questions designed to orchestrate reflective discussions about the simulations.

As such, we conjecture that these students' engagement in the instructional activities played an important role in their developing such a scheme. For instance, we had students practice imagining and describing a coordinated multi-level process that gives rise to sampling distributions (and to the simulations' results):

- Level 1: Randomly select items to accumulate a sample of a given size from a population. Record a sample statistic of interest.
- Level 2: Repeat Level 1 process a large number of times and accumulate a collection of statistics.
- Level 3: Partition the collection in Level 2 to determine what proportion of statistics lie beyond (below) a given threshold value.

In classroom discussions the instructor employed a metaphor designed to help students distinguish and coordinate these different levels. The metaphor entails imag-

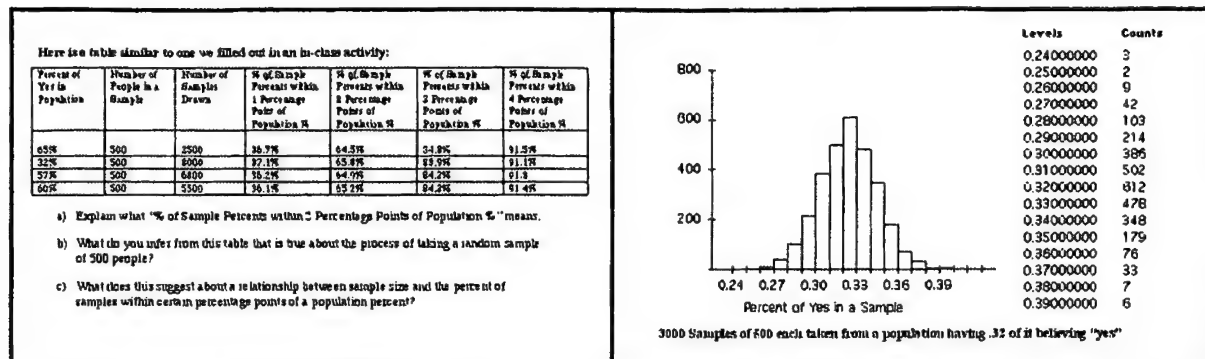

Figure 2. Part of an instructional activity designed to structure students' investigation of the relationship between sampling distributions and underlying population proportions. Students filled out the table on the left by organizing information (like that shown on the right) generated by computer simulations of drawing many random samples from populations with given proportions.

ining a collected sample of dichotomous opinions (“yes” or “no”) in Level 1 as a box containing “1”s (for “yes”) and “0”s (for “no”). It then entails labeling the box with a “1” (or a “0”) if the proportion of its contents is greater (or less) than a given threshold value. In this metaphor, what accumulates in Level 2 is a collection of “1”s and “0”s (or boxes/slips of paper labeled “1” or “0”), each of which represents a sample whose statistic is greater (less) than the threshold value. At Level 3, the metaphor entails calculating the percent of the collection of “1”s and “0”s in Level 2 that are “1” or that are “0”, depending on the required comparison.

The following excerpt illustrates one student's coherent image of the multi-tiered sampling process, the development of which appeared to have been facilitated by his use of this metaphor. We take this student's coherent image as an expression of the stable scheme of conceptual operations characterized above. In the excerpt, the student (D) interpreted a sampling simulation's command and the result of running it as he viewed familiar simulation windows on a computer screen (see Figure 1)<sup>2</sup>:

D: Ok. It's asking...the question is...like “do you like Garth Brooks”. You're gonna go out and ask 30 people, it's gonna ask 30 people 4500 times if they like Garth Brooks. The uh...(talks to himself) what's this? let's see...the actual...like the amount of people who actually like Garth Brooks are...or 3 out of 10 people actually prefer like Garth Brooks' music. And uh...for the 30...when you go out and take one sample of 30 people, the cut off fraction means that if you're gonna count, you're gonna count that sample, if like 37% of the 30 people preferred Garth Brooks. And then it's going to tally up how many of the samples had 37% people that preferred Garth Brooks. So like the answer would be I don't know, like whatever, 2000 out of 4500 samples had at least 37% of people preferring Garth Brook.

[...]

I: How was it that you thought about it that allowed you to keep things straight?  
[...]

D: I just thought of it like ... I don't know, I sort of thought of it like how you were saying. Like...if the like 1s and the 0s if you ask 30 uh if like 10 of them say they like Garth Brooks-- or for every person who likes Garth Brooks you put a 1 down, if they don't you put a zero. You do that 30 times and you're gonna get like I don't know, 15 ones and 15 zeros you add up, you add them up. Then it says the cutoff fraction for each sample is 37% so you have like at least 37% of the...like those or...30-- if you add it up and divided it by the 30 and it's at least 37% then you have like another pile of like little papers and you put a one on like the big, the big one for the sample or a zero if it's less than-- if the whole sample is less than 37%. The 1s and 0s I don't know...you said something about like...that sort of helped.

A significant feature of student D's thinking was his ability to clearly distinguish different levels of the resampling processes — never confounding the number of people in a sample with the number of samples taken — while coordinating the various levels into a structured whole. Additionally, and relatedly, student D interpreted the result of the simulation as an amount (percentage) of *sample proportions*, thus suggesting that he understood that the multi-level process generated a *collection* of sample proportions.<sup>3</sup>

Student D's coherent image contrasts sharply with that of many poorer-performing students who persistently confounded numbers of people in a sample with numbers of samples drawn. The following interview excerpt illustrates one such student's (M) difficulties in the context of explaining similar computer simulations:

### Segment 1

I: Ok, Suppose that, here's what I'm gonna do, uhh instead of 4500 samples I'm gonna take uhh, 1000 samples. Everything's gonna stay the same — sample size is 30, population fraction is 3/10ths, but now were' just taking 1000 samples. What would you expect the results to be?

[...]

M: Uhh, somewhere around like (short silence), hmm around like 25-30% of those 1000 samples.

I: Why 25-30%?

M: Because it's uhh...easier to uhh, I mean

I: What are you basing that judgment on?

M: Uhh, the actual population percentage, of 30

I: Ok, so you figure it'll be about 30%, 25 to 30, because the population fraction is 30%?

M: Yeah, somewhere close to that.

[...]

## Segment 2

I: Alright (runs simulation, result displayed on output screen is "189 of these 1000 repetitions ...")

M: 2/10ths, 20%. Hmm, it's still a little less

I: So it's a little less than 20%, right?

M: Hmm hmm, huh (seems surprised)

[...]

## Segment 3

I: Alright. Suppose that now we, let's do this, let's make 2500 samples (changes parameter value in command window). What fraction of those samples, I mean what result would you now expect, for the number of samples that we're going to get that exceed 37% preferring Garth Brooks?

M: About 1/5 of those.

[...]

I: Now, before you would have said "well, 3/10ths of the 2500 samples, the 2500 repetitions"

M: Hmm hmm

I: Do you still sort of lean that way, that you should get around 3/10ths of the --?

M: I think it should, but I don't understand why it's not, why it keeps coming out with 1/5<sup>th</sup>

rather than 1/3<sup>rd</sup>.

I: Alright, what is that "3/10ths" 3/10ths of?

M: Uhh, hmm 3/10ths of the entire population

I: Alright, and those are people, right?

M: Hmm hmm (nods)

I: Now, if you took 3/10ths of the 2500 repetitions you're taking 3/10ths of what?

M: Of the uhh...people sampled (chuckles)

I: No, 3/10ths of the *samples*.

M: Oh. Hmm hmm

Segment 1 of the excerpt suggests that student M expected the simulation to produce an amount (number) of samples and that he expected the percentage of that amount to hover around the sampled population percent (30%). Segment 2 illustrates his surprise at finding the actual percent being 20% of the 1000 samples generated. In segment 3 the student anticipated the same (20%) result for a simulation involving a larger number of samples, but he did not understand why this should be so because his conviction was that the simulation should produce a numerical value close to the sampled population percentage. The remainder of the segment reveals that student M had been interpreting the simulation's result as a percentage of people sampled rather than as a percentage of samples.

During such instructional activities most students experienced great difficulty conceiving the re-sampling process in terms of distinct levels. They would often unwittingly shift from speaking and thinking of a number of people in a sample to a number of samples selected. Their control of the coordination between the various levels of imagery was unstable; from one moment to the next their image of a number of samples (of people) seemed to easily dissolve into an image of a total number of people. These difficulties led many students to misinterpret a simulation's result as being about a percent of people rather than about a percent of sample proportions. This muddling of the different levels of the resampling process, in turn, obstructed their ability to imagine how sample proportions might distribute themselves around the underlying population proportion.

A salient consequence of these students' difficulty in imagining a sampling distribution was their tendency to judge a sample's representativeness only in relation to the underlying population proportion. Their image of sampling did not entail a sense of variability that extended to ideas of distribution: they understood that sample statistics vary, but only to the extent that if we were to draw more samples and compute statistics from them, those statistics would differ from the ones for the samples already drawn. Thus, judgments of a particular sampling outcome's unusualness were based largely on how they thought the outcome compared to the underlying population parameter per se, instead of on how it might compare to the way similar sample statistics were clustered around the parameter.

On the basis of such characteristics, we conjecture that these students' encompassing image of sample was *additive* — that is, in these instructional settings they tended to view a sample simply as a subset of a population and to view multiple samples as multiple subsets.

A contrasting image of sample is suggested in the following excerpt of student D explaining the purpose of simulating resampling:

- D: If like...if you represent-- if you give it like the split of the population and then you run it through the how-- number of samples or whatever it'll give you the same results as if-- because in real life the population like of America actually has a split on whatever, on Pepsi, so it'll give you the same results as if you actually went out, did a survey with people of that split.
- I: Ok, now. What do you mean by "same results"? On any particular survey at all--you'll get exactly what it-?
- D: No, no. Each sample won't be the same but it's a...it'd be...could be close, closer...
- I: What's the "it" that would be close?
- D: If you get...if you take a sample...then the uh...the number of like whatever, the number of "yes"s would be close to the actual population split of what it should be.
- I: Are you guaranteed that?
- D: You're not guaranteed, but if you do it enough times you can say it's within like...1 or 2% of error depending upon uh how many times-- I think-- how many times you did it.

The resemblance between sample and population was clearly foremost in student D's mind, but his image was of a *fuzzy* resemblance bound up with ideas of variability and proto-distributional images of a collection of sample proportions. He did not expect a sample to be an exact replica of the sampled population, instead he anticipated that in repeating the sampling process many sample proportions would be "more or less" close to the population proportion. Moreover, student D's confidence in a sample's representativeness was based on this anticipated image of how a collection of similar sample proportions might be distributed around the population proportion.

We put that student D's description is consistent with his having conceived a sample as a quasi-proportional mini version of the sampled population, where the "quasi-proportionality" image comes from anticipating a bounded variety of outcomes, were one to repeat the sampling process.

It is often useful to refer to a germinating idea with suggestive terminology; we call this image of sample a *multiplicative conception of sample* (MCS) because its constitution entails conceptual operations of multiplicative reasoning. An elaboration of multiplicative reasoning (Harel & Confrey, 1994) is beyond the scope of this paper. For the present discussion we draw on Inhelder and Piaget's (1964) broad characterization of multiplicative reasoning as conceiving an object (quantity) as *simultaneously* composed of multiple attributes (quantities). For instance, conceiving a proportion involves multiplicative reasoning when it entails comparing two quantities in such a way as to think of the measure of one in terms of the measure of the other (Thompson

& Saldanha, in press). An example is when one thinks of percentage as quantifying a part of a whole *in terms of the whole*. This conception entails keeping both the part and the whole simultaneously in mind and the ability to reciprocally relate and express one in terms of the other. This is different from thinking of measuring a subpart of a whole only in absolute terms.

We hypothesize that MCS entails multiplicative operations on several levels: on one level it entails conceiving a relationship of proportionality between a sample and a population. On another level, imagining the emergence of a *proto*-distribution of sample statistics entails structuring statistics as subclusters of the range of an entire collection of statistics. This involves fractional reasoning. Finally, a mature and well articulated image of distribution supports quantifying the expectation of a particular kind of sampling outcome and thus quantifying one's confidence in a sampling outcome's representativeness. This entails the operation of juxtaposing the individual sample result against an aggregate of similar sample results to compare the one against the many – an image of simultaneity that is central to multiplicative reasoning.

### Conclusion

Though our elaboration of these two images of samples and sampling is empirically grounded, our point in presenting it is not to imply that students in our experiment fell into one or the other camp. Rather, our point is to highlight two significantly different conceptions and images of samples and sampling — perhaps exemplary of extremes in a continuum of students' conceptions — that provide insight into what may be more or less powerful conceptions to target for instruction.

From our perspective, there are two reasons why the distinction between the additive and multiplicative conceptions of sample is significant. First, in contrast to the additive conception, MCS entails a rich network of interrelated images that supports a deep understanding of statistical inference. In practice, statistical inferences about a population are typically made on the basis of information obtained from a *single* sample randomly drawn from the population. This practice is common among statisticians despite expectations of variability among sampling outcomes. In statistics instruction, however, it is uncommon to help students conceive of samples and sampling in ways that support their developing coherent understandings of *why* statisticians have confidence in this practice. We claim that MCS empowers students to understand the *why* by orienting them to relate individual sample outcomes to distributions of a class of similar outcomes. In the same way, MCS enables students to consider a sampling outcome's relative unusualness. As such, we propose that MCS characterizes a powerful “target” conception that can guide efforts to design instructional activities and student engagements intended to support their developing a deep understanding of sampling and inference.

The second reason why we consider the distinction between these two conceptions of samples to be significant is that few of our students developed MCS. Instead,

most students seemed to tend toward an additive image of sample. To us, this state of affairs suggests that developing MCS is non-trivial. The reasons for students' difficulties in this regard are currently unclear to us. However, one plausible hypothesis grounded in our data is that for many students the simulation and sampling distribution activities were of such a complexity so as to essentially overshadow ideas of sampling variability highlighted in the first phase of the teaching experiment. In a subsequent teaching experiment (Saldanha & Thompson, 2001) we took this hypothesis seriously and engaged students in instructional activities designed to support their developing a MCS.

### Notes

<sup>1</sup>Research reported in this paper was supported by National Science Foundation Grant No. REC-9811879. Any conclusions or recommendations stated here are those of the authors and do not necessarily reflect official positions of NSF

<sup>23</sup>Similar samples share a common size, selection method, and parent population. Furthermore, they are selected to obtain information about a common population characteristic.

<sup>4</sup>The simulation was of sampling people's preference for a particular musician from a hypothetical population having a known proportion of it preferring the musician

<sup>5</sup>We note that student D's prediction of the simulation result was highly inaccurate in this excerpt. Shortly thereafter, however, he quickly revised his prediction with a highly accurate one and continued to make such accurate predictions throughout the rest of the interview. We thus believe that his initial prediction was not an indication of a poor sense of how the sample proportions were distributed, rather it was merely the result of his focus, in the moment, on explaining *how* the simulation worked and *what* it generated.

## USING MULTI-REPRESENTATIONAL COMPUTER TOOLS TO MAKE SENSE OF INFERENCE

Hollylynne Stohl  
North Carolina State University  
Hollylynne@ncsu.edu

James E. Tarr  
University of Missouri  
TarrJ@missouri.edu

We report how two sixth-grade students used software tools to formulate and evaluate inferences based on simulation data. Students' interactions were analyzed during a 12-day instructional program that utilized *Probability Explorer* software as a primary investigation tool. A variety of microworld tools enabled students to recognize the importance of using larger samples to draw valid inferences. Vignettes from three instructional tasks are included.

In recent years, the National Council of Teachers of Mathematics (NCTM) (2000) has advocated that *all students* develop and evaluate inferences that are based on data. Specifically it is recommended that "upper-elementary and early middle grades students... begin to develop notions about statistical inference" (p. 50) and suggest the use of computer simulations to facilitate student learning in probability. Investigating students' probabilistic reasoning with technology tools, however, is a recent endeavor (e.g., Pratt, 2000; Drier, 2000a, 2000b). In fact, there exists a gap in knowledge of early adolescent learners' development of probabilistic reasoning with open-ended multi-representational software. Our research sought to determine the role technology tools plays in students' development of the notion of statistical inference. In this paper, we report how two students used software tools to formulate and evaluate inferences based on data from simulations.

### Theoretical Perspective

The framework for our research is based on a coordinated perspective of learning. In particular, we believe that learning is a constructive process of resolving perturbations through reflection and abstraction (von Glasersfeld, 1995), occurs within a social context in which meanings are negotiated through interactions with other cognizing individuals (Voigt, 1996), and is enabled and constrained by tools and resources within the environment (Graue & Walsh, 1998). We believe that the intended and enacted mathematical tasks, students' interactions with microworld tools, and the social interaction among students and between students and teachers, all operate as potential meaning-making agents for the development of probabilistic reasoning. Thus, this constructivist framework guided the design of the microworld tools, instructional tasks, and classroom teaching throughout our research.

Several researchers (e.g., Battista, 1998; Biddlecomb, 1994; Land & Hannafin, 1996) have worked with children and developed principles for designing and using open-ended computer microworlds to facilitate students' construction of knowledge.

Biddlecomb (1994) emphasizes that “computer environments must be very flexible in order to make them as open as possible for the teacher and students to construct their own individual and shared mathematical environments” (p. 91). A well-designed open-ended learning environment (OELE) enables learners to build and test their intuitive notions in an exploratory manner such that their understanding evolves as a continuous and dynamic process through observation, reflection, and experimentation (Land & Hannafin, 1996). *Probability Explorer* (PE) (Stohl, 1999-2002) is purposefully designed as an OELE with multiple ways to represent data that engage students in designing, simulating, and analyzing results of probability experiments. At a fundamental level, data is represented in *PE* with randomly generated icons that can be sorted, stacked (in a pictograph) or lined up in the sequence in which they occurred. A Pie Graph (relative frequency), Bar Graph (frequency), and Data Table (counts, fractions, decimals, and percents) are also available to display results dynamically changing during a simulation (see Figure 1).

Students can use *PE* to develop their abilities to conjecture and evaluate inferences when they have opportunities to explore a variety of probability situations, determine

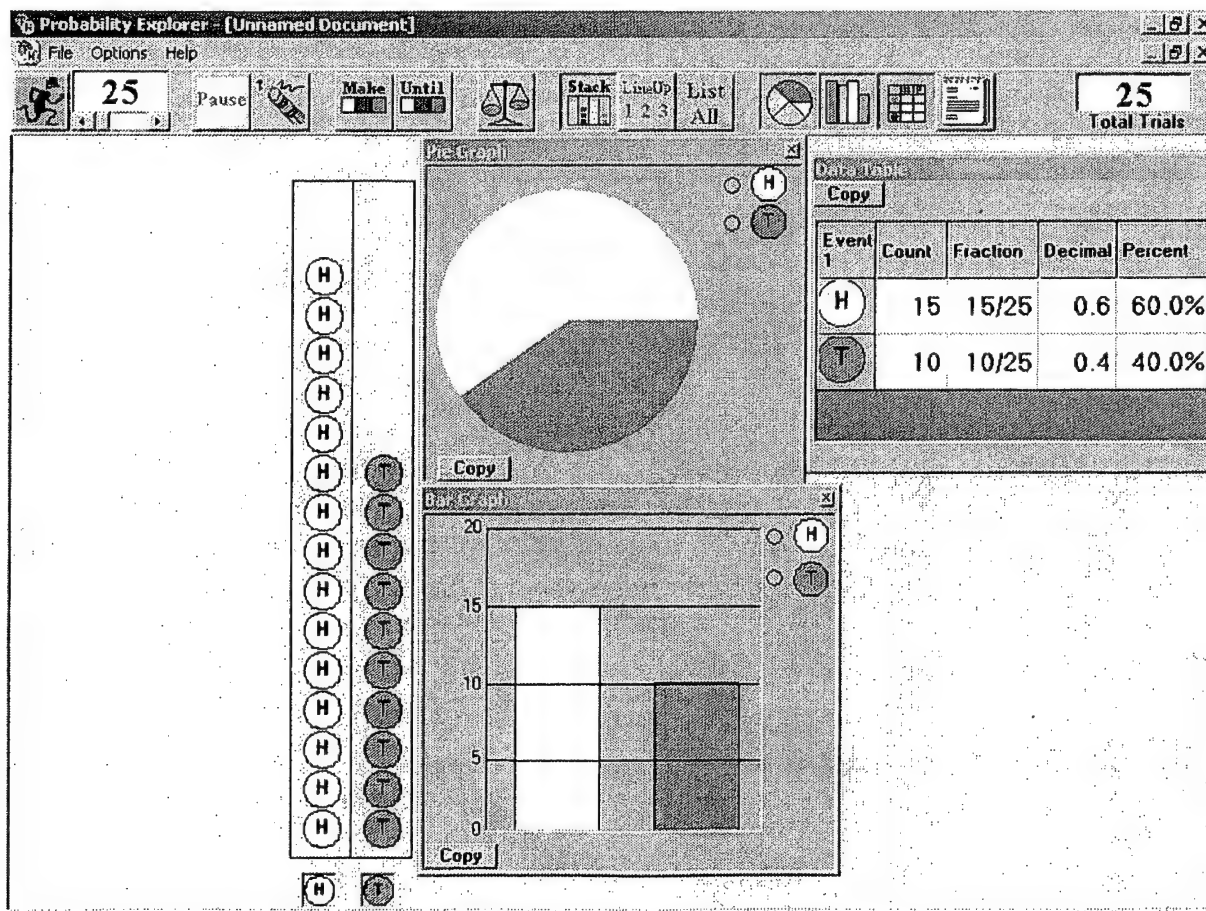

Figure 1. Data displays of 25 tosses of a fair coin.

how many trials to run, and choose which tools to use to analyze data. One of the most important aspects of formulating and evaluating inferences is understanding the *unpredictability* of random phenomenon in the short-run but *predictability* in the long-run trends in data (i.e., the law of large numbers). Thus, the sample size in a simulation becomes an important factor for students to consider when making inferences from a sample distribution to the population and making connections between empirical and theoretical probability. Prior research has shown the difficulty students experience in reasoning consistently about the effect of sample size. Fischbein and Schnarch (1997) found that students' acceptance of the use of small sample sizes increased dramatically from 5<sup>th</sup> to 11<sup>th</sup> grade. They hypothesize that "this misconception is based on the idea that a ratio is representative of an indefinite pair of numbers" (p. 101). Stavy and Tirosh (2000) attribute this erroneous conception to an intuitive rule based on "Same A - Same B" by which students assume that if the results are in the same proportion then the chance of each result occurring is the same. Stavy and Tirosh also found that students' use of this intuitive rule seems to become more prominent with age and as their ability to recognize proportionality stabilizes.

Research on instruction aimed at helping students develop intuitive notions about sample size has shown to positively effect students' understanding about the power of sampling in making inferences. Metz (1999) found that, after the provision of extensive experiences in designing, implementing, and critiquing investigations within a science context, 41% of second, fourth, and fifth grade students made arguments for the use of large samples to make inferences about a population. In a study with sixth grade students, Aspinwall and Tarr (2001) found that prior to instruction, 5 of their 6 case study students showed no or little awareness of the relationship between experimental probability and sample size, and typically thought that any size sample should reflect the parent distribution. Their analyses indicated that game-like situations in which the chance of winning is unequally distributed between players helped students to understand the role sample size plays in making probability judgments. Students learned that outcomes with smaller probabilities are more likely to win with a small number of trials while outcomes with higher probabilities are increasingly favored as the number of trials increases.

Using computer tools and representations provides students with different ways to simulate and interact with data to make inferences. In prior research with *PE*, Drier (2000a, 2000b) found that fourth-grade students used the representations in *PE* as both objects to display and interpret data, and as dynamic objects of analysis during experimentation to develop a notion of the "evening-out phenomenon." These students recognized that larger number of trials resulted in distributions that closely resembled what they expected from the theoretical probabilities based on how they had designed an experiment. Pratt (2000) also found that 10-year old students working with a *Chance-Maker* microworld made a connection between the number of trials and the distribution of data (viewed in pictographs and pie graphs) and that they could

use a “workings box” to control the theoretical probability, which also affected the distribution of data. The findings of both Pratt and Drier suggest that simulation tools that give students control over designing experiments, running as many trials as they desire, and viewing graphical representations of results may help in the development of deeper understandings of how theoretical probability, empirical probability and sample size can be used to make inferences.

Considering our theoretical perspective on learning in a technological environment and the implications from prior research, we sought to explore the following questions in our focused analysis of two case students:

- How do these students use *Probability Explorer* tools to simulate experiments and analyze data as part of their meaning-making processes in solving a variety of probability tasks?
- How do these students socially negotiate an understanding of the interplay of theoretical probability, empirical probability and sample size, and use these understandings and computer-based tools to conjecture and justify inferences based on data?

### **Methods of Inquiry and Data Sources**

This research report focuses on two average-level sixth-grade students who participated in a larger study of 23 sixth-grade students in an average-level mathematics class in an urban, southern public middle school. Prior to instruction, in collaboration with the regular classroom teacher, we purposively selected (Lincoln & Guba, 1985) Manuel (Hispanic male) and Brandon (Caucasian male) to serve as one of three case study pairs. These students were chosen to reflect the ethnic and socioeconomic diversity within the class and were representative of average-level mathematical achievement based upon scores on standardized tests in mathematics as well as a pre-instructional test in probability.

### **Research Setting and Data Sources**

All students were seated in pairs at tables in their regular classroom with a PC laptop, calculators, and manipulative materials (e.g., dice, spinners) readily available. Manuel and Brandon’s laptop computer was connected to a PC-to-TV converter to internally video-record their computer interactions while microphones captured their conversations. We used video recording because it is particularly useful in trying to access students’ construction of mathematical understandings (Pirie et al., 2001) and gave us a direct record of how they used the computer tools. For this paper, additional data from the instructional sequence was used in the analysis. In particular, the whole-class video, students’ written class work and homework assignments comprised the data corpus.

## Instructional Program

We developed and co-taught a 12-day probability unit utilizing *PE* as a primary investigation tool. Several characteristics were common to the instructional tasks. Problem tasks represented random phenomena that occur in a variety of contexts (e.g., pulling fish from a lake, selecting marbles from a bag). Typically instructional tasks required students to model the phenomena, carry out simulations using *PE*, and collect, display and analyze data in order to draw appropriate inferences and formulate convincing arguments based on data.

The design and implementation of our instructional program were influenced by the Mathematics Teaching Cycle (Simon, 1995). We utilized this conceptual framework to create purposeful pedagogy that reflected our goals for student learning yet was responsive to students' ideas and practices. More specifically, we generated hypothetical learning trajectories prior to instruction and made adaptations based on our ongoing assessment of students' probabilistic reasoning. In this regard the design of our curriculum was an iterative process based on student interaction with the instructional tasks, microworld tools, and the teacher-researchers.

## Methods of Analysis

To understand the interactions that comprise students' meaning-making processes, our research draws upon an interpretivist approach to inquiry (Graue & Walsh, 1998) using a case study method (Stake, 1995). In particular, we used qualitative research methods to observe and critically analyze students' probabilistic reasoning, meaning-making processes, and social and computer interactions while using *PE*. An analytic model for examining videotape data (Powell, 2001) was used to study the growth of students' probabilistic reasoning and their use of computer tools. More specifically, this method was used to identify critical events (or conceptual leaps) and the interactions that elicited such critical events.

## Results

For the purpose of this paper, we included an analysis of Brandon and Manuel's use of *PE* tools on three instructional tasks. In the first task, students used features of *PE* to estimate the distribution of marbles in a mystery bag. In the second task, they used *PE*'s Weight Tool feature to design a simulation model for a given spinner and to validate their model. In the third task, they used repeated simulations of various sample sizes to determine whether a die was fair and to estimate the probability of each number on the die occurring. Throughout these tasks, Brandon and Manuel used several *PE* tools in making informal inferences based on their developing understanding that simulations and data analysis should inform their judgments. The results presented below illustrate how their ability to design and simulate experiments, use various microworld tools, support inferences with data, and formulate convincing arguments developed across the tasks.

**Mystery Marble Bag Task**

On the 4<sup>th</sup> day of instruction, students used *PE* to collect and analyze data in order to draw inferences regarding the composition of a bag containing 10 marbles. Brandon and Manuel chose the Run Until tool as a novel heuristic in their problem solving. (The Run Until tool allows users to select an outcome and run a simulation until that outcome occurs). They effectively used Run Until in two distinct ways. First, by repeatedly sampling one marble with replacement they inferred which colors of marbles were most likely *not* in the bag; and second, in deciding which colors were certainly present. The following excerpt reveals both uses of Run Until.

Brandon: Wait. Wait. Wait. This is what you do: Run experiment until you get an outcome of white. Do Run Until so you can see if there are any whites. [After 17 trials with no white outcomes] I don't think there are any whites in the bag -- zippo!

Teacher: Why do you say that?

Brandon: [As marbles continue to be sampled with replacement] Because we're running 30 trials and there's no whites!

Manuel: So far and we've run it until there's a white. [After Run Until yields no green outcomes in 76 trials, they use Run Until black] Well what do you know? No black!

Teacher: Why do you say that? You've done it (only) 14 times.

Manuel: [As marbles continue to be sampled with replacement] Make that 25 -- No, 30!

Teacher: At what point... do you have enough evidence to say, "There's no black"?

Both: Because you've run it 50 times!

Teacher: But you were saying that back at 10 (trials).

Brandon: Well, that was our guess. Now we're for sure (right). Now we're very confident and that was the goal, to be very confident.

Manuel: I know what the colors are: Red, yellow and blue!

On the subsequent day, Brandon preselected a distribution of 12 marbles. Manuel's goal was to estimate the composition of the bag. He made efficient use of Run Until since he only needed to use Run Until once to decide which colors were and were not in the bag. After 140 trials yielded no white outcomes, the sample continued to grow to 500 after which Manuel observed that it contained no green or yellow marbles. Moreover, he remarked that only red, yellow and blue marbles comprised the set of 500 outcomes. After concluding that only these three colors were present in the

bag, Manuel subsequently ran several sets of 10 trials and used an informal approach for inferring the number of marbles of each color by estimating a mean of the most commonly observed frequencies.

In this task, Brandon introduced the use of the Run Until tool as a strategy, but Manuel quickly realized how the data was providing relevant information. It is interesting that Manuel only used a large number of trials with the Run Until tool as evidence to infer which colors were in the bag, but repeatedly used a small sample size (10) to make his inference about the distribution of colors of marbles. Since he knew that the bag only contained 12 marbles, the use of a large number of trials may not have helped him unless he could use proportional reasoning to infer the distribution based on percentages or the empirical distributions of colors. Although Manuel used a larger number of trials to infer which of the six colors were present in the bag, large numbers of trials would only be useful to find the distribution if he was able to use proportional reasoning which may not have been intuitive or accessible to him.

### Spinner Simulation Task

On the 9<sup>th</sup> day of instruction, Brandon and Manuel used the Weight Tool to create a model for a spinner (Figure 2). They used the Pie Graph as a primary representation to analyze data and test the “goodness” of their model and used decimals and percents in the Data Table as secondary representations. They mostly ran multiple sets of 100 trials and occasionally a larger number of trials. Consider the following two episodes that illustrate their meaning-making about the connection between theoretical and empirical probability using several *PE* tools.

#### Episode 1

A teacher-researcher challenged Brandon and Manuel to design a model of the spinner shown in Figure 2 using a total weight of 50. Manuel typed in 20:10:20 in the Weight Tool. Brandon claimed “that’s not right” and Manuel said, “I bet you a billion dollars it is.” The teacher-researcher asked Manuel to convince Brandon that

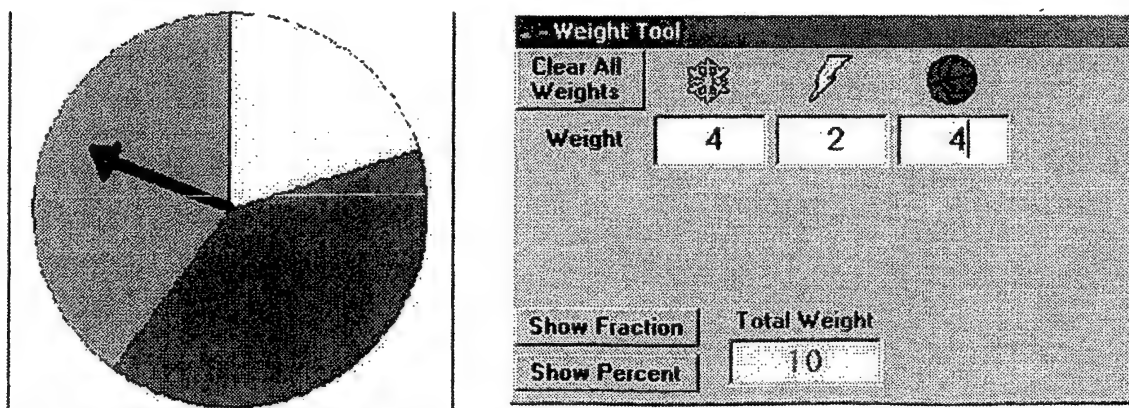

Figure 2. Spinner and weights used in *PE*.

20:10:20 could be used to model the spinner. Manuel struggled to explain how the weight model was in proportion to the original weights of 4:2:4 or the spinner regions. Brandon decided to run simulations in *PE* to “see if it still comes close, as long as we have the same percentages.” He ran 100 trials with the Pie Graph and Data Table open and after 60 trials said, “That looks pretty right.” When the 100 trials were complete [showing a 34:23:43 distribution] he said, “Okay, that’s right.” Manuel interjected, “Yeah, I just don’t know how to explain it.” Brandon continued to run sets of 50 and 100 trials. After several sets of trials Brandon claimed, “Well, that is pretty close...” Well, he’s right cause I see the pie graph and I agree with him.” By comparing percentages of the theoretical probability in the Weight Tool with the empirical data shown in the Pie Graph and Data Table, Brandon seemed to understand that empirical data could be used to support or confute the notion that weights of 20:10:20 appropriately modeled the spinner. His use of 50 and 100 trials were not particularly large, but he *may* have been using these numbers since 50 is compatible with the total weight and 100 is convenient in reasoning about part-whole relationships in the Pie Graph. It is important to note that Brandon needed to run several sets of 50 and 100 trials before he was convinced that the empirical data supported that weights of 20:10:20 accurately modeled the spinner.

### Episode 2

The software application froze while they modeled a second spinner. The spinner and their initial weights are shown in Figure 3. Brandon restarted the application and redesigned the weights but mistakenly inserted a 5 (rather than 3) for the “rock” representing the green sector.

Brandon ran 100 trials and Manuel commented that the Pie Graph looked “way off” (sectors representing the Smiley Face and Rock were each about 40%). Brandon responded, “No sir!” and Manuel argued, “Yes, that is so off, let me look at the Weight Tool.” He opened the Weight Tool and remarked, “See? You did the wrong weights.

Figure 3. Second spinner and weights in *PE*.

Rock was supposed to be 3, that is why the pie (graph) looked funny.” Although Brandon used empirical data to test the weights used for the first spinner, it was Manuel who seemed to make the connection between the empirical data and the weights and was able to apply his understanding when the Pie Graph did not appear as he expected. In this task, both students made sense of how empirical data could be used to test a conjecture. This type of meaning-making is an important component to being able to use empirical data from a large number of trials to make inferences. The subsequent task in the instructional sequence (*Schoolopoly*) required students to make inferences regarding the fairness of a die and support their claim with evidence (i.e., data).

### Schoolopoly Task

On the 10<sup>th</sup> and 11<sup>th</sup> days of instruction, Brandon and Manuel sought to investigate claims that a company manufactured faulty (biased) dice. Unbeknownst to them, weights of 2-3-2-3-2-3 were preloaded into the Weight Tool for the outcomes, 1-6, respectively. Their assignment was to collect evidence to support or reject claims that the die is biased and to estimate the theoretical probability of each outcome, 1-6. On Day 10, they began by running a total of 51 trials; they noticed that 5 occurred only three times and this result focused their attention on the number of 5s in a subsequent set of 500 trials. While the simulation ran, they repeatedly commented on the low number of 5s and 1s in relation to the other frequencies and hypothesized that these outcomes were relatively difficult to obtain. Manuel decided to run 50 (new) trials and used the Data Table and Stack column to analyze data. This set of data yielded many 5s leading Brandon to argue that the die was indeed fair. Manuel ran a second set of 50 trials with a 9-6-4-11-9-11 distribution which led Brandon to announce “dang this is fair.” His notion of fairness was grounded in the observations of indiscernible patterns in the sample distributions from relatively small sets of data. Brandon and Manuel concluded Day 10 by writing that they believed their die was fair.

At the start of Day 11, Brandon had control of the mouse and set the number of trials to 300 because it represented a large multiple of 6. As the simulation ran, they monitored the relative frequencies displayed in the Data Table, Pie Graph and Bar Graph. At 60 trials, with few 5s occurring (represented in red on the Pie Graph and Bar Graphs), Brandon cheered, “Come on! Get even red!” then remarked, “I think it’s actually fair” and dismissed the non-uniform sample distribution by arguing, “5 just got off to a bad start.” As the simulation of 300 trials neared completion, Brandon concluded, “It’s pretty fair... It’s only 5 and 3 and 1 are a bit behind” (pointing to sectors in Pie Graph). Upon reflection, Brandon altered his belief about fairness and stimulated the following discourse:

Brandon: I really don’t think it’s fair.

Manuel: [In disbelief] Why?

Brandon: Just because, I --

Manuel: Every single thing doesn't have to be even, man, it's the luck. They are pretty much close.

Brandon: Yeah, you're right. Let's just do another 500 (trials).

Manuel: Let's do one million.

Brandon: No, let's do 6000. [Manuel sets the number of trials to 500] Now run it once. [Manuel hits Run] Now click 500 one more time.

Manuel: I want to do the Pie Graph [opens Pie Graph, then Bar Graph, and Data Table at about 400 trials].

Brandon: I still think that 1... 5 is continuously behind.

Manuel: If you don't think this is fair... It's fair, man.

Brandon: But look at the 5 [There are 580 trials with distribution of 88, 115, 80, 108, 79, and 111]

Manuel: It doesn't all have to be perfect, man! No one is going to get theirs this way that much.

Brandon: [At 650 trials] Look at the percents: 13 (percent for 5), 13 (percent for 3)... I bet you that's (the weights of) 3, 3, 3, 2, 2, and 1.

Manuel: I bet you're wrong. I bet we're fair.

Brandon: I bet we aren't fair.

Manuel: Well, I don't care. We are fair. Just because it's not all even doesn't mean we're not fair. Dude, we're already up to 1000 (trials).

Brandon: But still, I really don't think... it's only beating it by about a hundred.

Manuel: It's not that unfair. [At 1300 trials] See 3 and 5 and 1 are practically the same.

Brandon: So they must have the same probability but that might have been more because (inaudible).

Manuel: [At approximately 1500 trials -- See Figure 4] Wait a second. Wait a second. We *are* unfair. These two... all of these [pointing to 1, 3 and 5] are (weighted) 1 and all of these [referring to 2, 4 and 6] are (weighted) 2. So 2, 4, 6. We're unfair.

Brandon: Thank you. I told you!

They continued to run sets of large trials (1500 or more) and determined that "6,

4, and 2 had higher probability than 5, 3, and 1" and estimated the probability for 1-6 occurring, as 14%, 20%, 13%, 20%, 13%, and 20%, respectively.

Students' use of software features (most notably displays of data) challenged their beliefs regarding fairness. More specifically, they learned to place value in sample distributions generated from larger sets of data. Specifically, Brandon monitored the sample distribution as the number of trials grew large; in doing so, he was able to reconsider the notion that "5 just got off to a bad start" and instead inferred that the die was biased. Similarly, Manuel used data to reject his initial belief that variation among a sample is attributed exclusively to randomness; he detected bias using patterns in data as the number of trials grew large. Together, they negotiated the inference about the die based on data collection, lengthy discussions, and analyzing patterns in data from increasingly larger samples of data.

### Discussion

Our research indicates that the instructional sequence and microworld tools successfully fostered students' ability to make appropriate inferences based on data. In

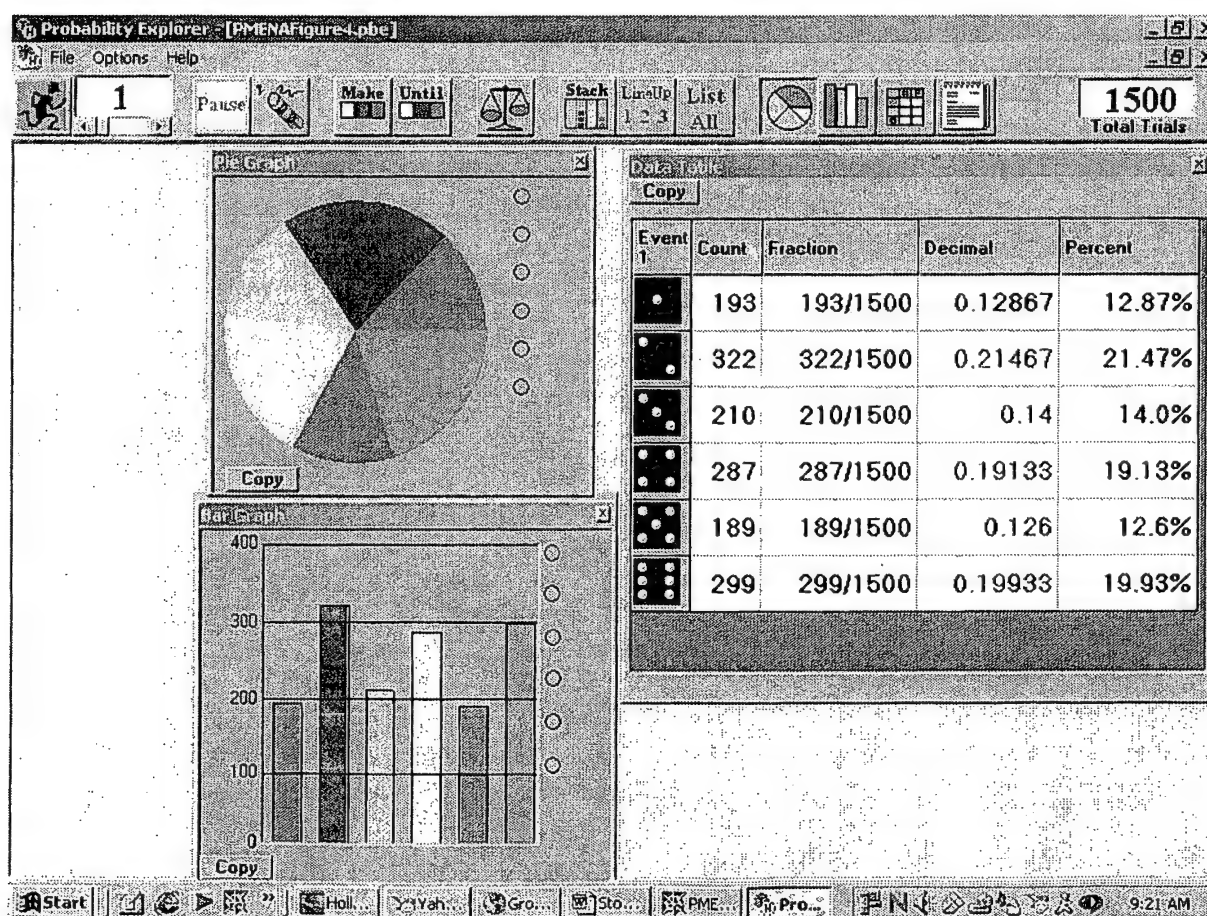

Figure 4. Data from simulation of *Schoolopoly* task.

particular, Brandon and Manuel's use of computer tools, coupled with social interaction, enabled them to make connections between simulation data (empirical probabilities) and weights in the Weight Tool (theoretical probabilities). Since the tasks were purposely designed to build toward a more powerful form of inference, their use of data to make inferences in each task was slightly different. The *Schoolopoly* task intentionally required students to make inferences about a population, which is more sophisticated than drawing inferences regarding the part-part distribution present within a bag of marbles. The intermediate task, *Spinner Simulation*, represented a purposeful attempt to transition students into part-whole reasoning through use of a pie graph representation. In addition, by grouping students in pairs or small groups, they were able to negotiate meaning of what constitutes evidence and, in particular, the role data plays in supporting arguments. Brandon's use of software tools (Pie Graph, percents in Data Table) to reason proportionally when making inferences enabled Manuel to make a transition from primitive reasoning into informal proportional reasoning.

Previous research (Fischbein & Schnarch, 1997; Stavy & Tirosh, 2000) indicates that students may not conceive the power of sample size because they invoke proportional reasoning and assume that every sample should be in proportion to (or reflect) the parent population. Such research, however, was based on written tasks that denied student access to simulation tools. Consistent with Pratt (2000) and Drier (2000a, 2000b), our results suggest that young adolescents can develop powerful notions about statistical inference when using simulation tools, recognize the importance of using larger samples in drawing valid inferences, and use data displays to make connections between theoretical and empirical probabilities. Further research needs to investigate whether sustained access to simulation tools and engagement in tasks about inference can help young students maintain notions of the effect of sample size even when their proportional reasoning stabilize at a later age.

## RANDOMNESS: RETHINKING THE FOUNDATION OF PROBABILITY

Yan Liu  
Vanderbilt University  
Yan.liu@vanderbilt.edu

Patrick Thompson  
Vanderbilt University  
Pat.Thompson@vanderbilt.edu

In this article, we highlight a series of tensions inherent to understanding randomness. In doing so, we locate discussions of randomness at the intersections of a broad range of literatures concerned with the ontological nature of probability theory, and epistemological conceptions of probabilistic ideas held by people. Locating the discussion thus has the advantage of emphasizing the growth of probabilistic reasoning and deep connections among its aspects.

Although we find no explicit definition of *randomness*, we might catch a glimpse of its meaning by looking at what texts say are the meanings of *random phenomenon*, and *random sampling*. Yates, Moore and McCabe (1998, p. 314) define a *random phenomenon* as one in which “individual outcomes are uncertain but there is nonetheless a regular distribution of outcomes in a large number of repetitions.” Bluman (2000, p. 632) defines a *random sampling* as one in which all possible samples of a certain size “must have an equal chance of being selected from the population.” As we shall elaborate below, these definitions are circular. In order for a student to understand them, they must already understand the idea of random variable and the distribution of its values, which itself entails an understanding of randomness. The problem, then, is that instruction is often designed to introduce students to ideas in ways that presume, essentially, that students already understand them.

Yet, surprisingly, we found little attention paid in statistics textbooks and research studies to what it means to understand randomness. Our analysis of secondary statistics textbooks (Thompson & Liu, 2002) revealed that 45% of questions concerning probability are stated, grammatically speaking, as if about a single, unrepeated (and hence non-probabilistic) event. Moreover, if students understand the phrase “at random” simply as “cannot predict ahead of time” or “unexpected”, then 98% of the questions can be interpreted as if about a single, unrepeated (and hence non-probabilistic) event. Yet, helping students understand “at random” productively is not explored. As Falk and Konold (1994) state, the complex nature of randomness poses an educational dilemma: “Shall we forgo discussing the meaning of the concept in our teaching (relying on students’ existing intuitions)? Or shall we endeavor to find a satisfactory way of presenting randomness, undertaking the challenge of bringing up the doubts and difficulties students will predictably have?” (Falk & Konold, 1994, p. 2).

### Randomness and Determinism

Ideas of randomness range along an ontological and epistemological spectrum. On one side of the spectrum, probabilities are regarded as not being inherent in objec-

tive nature but as reflecting human ignorance of a true determinist course of events. This view of probability was a product of the thinking of the European Enlightenment, the admiration for Newtonian mechanics, and the consequent belief in universal determinism. As Laplace (1814) remarked, "We ought then to regard the present state of the universe as the effect of its anterior state and as the cause of the one which is to follow." (p. 4). It is only a short step from this to the conclusion that absolute randomness does not exist, and therefore that all probabilities will be 0 or 1. The other end of the spectrum comes from the renunciation of determinism that was brought by quantum mechanics in the twentieth century. The understanding of Brownian motion as an expression of constant internal agitation of microscopic particles without external causes (von Plato, 1994), was taken as proving the existence of "irreducible chance" and therefore that randomness is an inherent feature of nature. "Causality, long the bastion of metaphysics, was toppled, or at least tilted" (Hacking, 1990, p. 1). von Mises concluded, "there exist genuinely statistical sequences in nature" (von Mises, 1957). However, controversies still exists as to whether randomness is a characteristic of a sequence itself or the process from which the sequence was generated. In *The Logic of Chance*, Venn said that it is 'the nature of a certain arrangement,' but not 'the particular way in which it is brought about,' that should be considered when judging a random arrangement, and the arrangement must be judged by what would be observed in the long run (Bennett, 1998, p. 166). Venn hoped to illustrate randomness by building a graph using the decimal expansion of  $\pi$ . From a deterministic perspective, however, even though the decimal expansion of numbers such as  $\pi$ ,  $e$ , and  $\sqrt{2}$  might exhibit disorderliness, the process from which each is generated is completely predetermined. Hence, for those who believe that randomness is a property of the process there exists no randomness in this situation. On the other hand, a sequence obtained from a random process may exhibit certain visible pattern in appearance. Thus, there is a necessary distinction between the idea of a random sequence and the idea of a sequence whose elements are chosen by a random process.

### Formalization of Randomness

von Mises' formulation of the notion of randomness was based on the intuition of "the impossibility of a gambling system". The randomness in a sequence lies in the "impossibility of devising a method of selecting the elements so as to produce a fundamental change in the relative frequencies" (von Mises, 1957). This definition of randomness had long been criticized as being "not mathematically expressible" and being "too inexact to serve satisfactorily as the basis of a mathematical theory" (McShane, 1970; Gillies, 2000). Kolmogorov and others later proved that von Mises-type sequences would exist if only simple formulas, rules, or laws of prediction are allowed. In other words, rather than requiring the randomness of a sequence to be judged by absolute unpredictability, Kolmogorov would require only unpredictability by a small set of simple rules. Kolmogorov further constructed a definition of random

sequence based on the notion of complexity in information theory: a random sequence is one with maximal complexity, in other words, a sequence is random if the shortest formula which computes it is extremely long (von Plato, 1994). The modern mathematical treatment of random process is based on Kolmogorov's measure theoretical probability. In his approach a random process (or stochastic process) is a family of random variables having time  $t$  as its independent variable. Kolmogorov distinguished random process from determined process by considering time and distribution of outcomes simultaneously: "If the state  $y$  of a system at time  $t$  is uniquely defined by its state  $x$  at an arbitrary moment  $t_0$  through a unique function  $f$  such that  $y=f(x, t_0, t)$ , situations of this general type are called *schemes of a well-determined process*. On the contrary, if the state  $x$  at time  $t_0$  only determines a probability distribution for the possible future state  $y$ , these are called *schemes of a stochastically definite process*" (von Plato 1994). Kolmogorov's solution to distinguishing between randomness and determinacy rests, however, on a troubling assumption: The function  $f(x, t_0, t)$  exists in its own right, which means that processes *have* certain properties timelessly, even if, over time, they vary.

### Implications for Teaching and Learning

Philosophical and mathematical debates on what "randomness" means highlight its deeply problematic nature and therefore highlight an equally problematic question of what "probability" means. Two approaches to addressing the issue are (1) ignore it and (2) try to bring the debate to students' levels. We propose a third approach, which addresses the problem by cutting the Gordian knot. We note that both ends of the spectrum presume that the question is ontological, that it is about what randomness *is*, and approach it by speaking of it as a property of something that exists, be it sequence, process, or distribution. We propose that instructional design finesse the question, focusing instead on what we might *mean* by randomness. That is, focus on the imagery and operations that support coherent thinking and reasoning about situations that we see as entailing randomness and that we hope students come to see as entailing randomness. One scheme of images and operations that we will describe in our presentation is that of students building an image of a loosely-coupled process with imprecisely-determined inputs that generate collections of outcomes that have predictable distributions in the long run but unpredictable distributions in the short run. We hasten to point out that we are not talking about adopting a perspective on the ontology of processes or collections. Rather, we are talking about helping students *imagine* processes and collections in a way that supports coherent stochastic reasoning.

**CONSTRUCTING GENERALIZATIONS: AN ANALYSIS OF ONE  
STUDENT'S PROGRESS TOWARD A GENERALIZED  
UNDERSTANDING OF THE LAW  
OF LARGE NUMBERS**

Joseph F. Wagner  
University of California, Berkeley  
jwagner@socrates.berkeley.edu

Knowledge transfer, traditionally defined as the successful use of knowledge learned in one situation in a different situation, has a long and controversial history. While in pragmatic terms the bulk of formal education in the U.S. is predicated on the assumption that transfer takes place, it has been notoriously difficult to demonstrate in research studies, particularly those in the cognitive tradition (Bransford & Schwartz, 1999). One of the reasons underlying the controversy and mystery of transfer is the lack of specificity with which the word has been used. The present research considers transfer of one particular kind: the ability to understand and interpret a variety of problem situations as supporting the application of a single mathematical principle. I use the techniques of microgenetic analysis (Schoenfeld, Smith, & Arcavi, 1993) to examine how one undergraduate student came to see a series of mathematics problems as "alike" as she constructed an understanding of the law of large numbers.

Many theories of transfer and analogical reasoning are grounded in assumptions involving structured mental representations. Specifically, most cognitive theories assume that individuals construct mental representations or schemata structured at an appropriate level of abstraction so as to be recalled and applied across relevant situations and contexts (see, for example, Gentner & Markman, 1997; Gick & Holyoak, 1980; Reed, 1993). Research in situated cognition offers an alternate approach by interpreting transfer as the result of an individual's attunement to affordances that support invariant activities across situations (Greeno, Moore, & Smith, 1993). The present research examines the kind of fine-grained data necessary to support the analysis and critique of these theories. I offer the beginning of an understanding of transfer that is consistent with the epistemological perspective taken by diSessa (1993) and diSessa and Sherin (1998). In this analysis, the development of scientific and mathematical knowledge takes place through systematization, reorganization, and integration of often context-sensitive, intuitive knowledge. The resulting knowledge systems permit greater flexibility than the more structured mental representations posited by traditional theories. This approach complements the perspective taken by Greeno et al. (1993).

Data for this research were taken from audio- and video-taped sessions recorded over a period of eight weeks as Maria, an undergraduate student, was enrolled in an introductory course in statistics. Maria was one of six students who agreed to meet

with me one-on-one for a series of two-hour, weekly sessions that were divided into two parts. During the first hour, students were invited to use me as a resource or tutor as they worked on the material of the course; during the second hour, students agreed to take part in other course-related activities that I provided for them. These activities included interviews, think-aloud problem-solving sessions, explorations with computer simulations, and simple empirical experiments using dice or other random devices. Thus, aspects of the sessions resembled classical clinical interviews. At the same time, students had significant motivation to learn during the interviews, since they would be held responsible in their coursework for the concepts we discussed.

The data considered here were taken from three sessions during which Maria worked on a variety of problems involving the law of large numbers and the central limit theorem. The Coin Problem, for example, asked if it would be to her advantage to flip more times or fewer times if she wanted a series of flips to land “more than 70% heads,” or “between 40% and 60% heads.” The Post-Office Problem asked if it was more likely for a post office with more or with fewer customers to find that the average height of the men arriving on a particular day to register for the draft was significantly above the national average height. Maria considered five such problems in all, involving different cover stories and contextual details, different problem types (some involving proportions, others involving means), and different aspects of the central limit theorem (some desiring nearness of a sample statistic to a population parameter, others desiring a deviation from it). Upon her first exposure to the problems, Maria approached them all differently, answering most of them non-normatively. During the course of the three sessions, however, she eventually came to see them as “alike” as she constructed an understanding of the law of large numbers that gradually came to encompass all of them.

Despite the fact that Maria could state the law of large numbers informally in what she called her *rule* (“The more you flip, the closer you get to what’s expected.”), a fine-grained analysis of Maria’s work on the Coin, Post Office, and other problems reveals that different problem contexts, problem types, and problem aspects consistently cued different language and different explanatory and descriptive ideas. The processes by which Maria came to see the problems as alike and their solutions as guided by a single principle took place only gradually and with the assistance of computer simulations, some questioning by the instructor, and explicit problem comparisons. However, these processes are not readily explained by theories that suggest Maria merely acquired a particular schema or applied an appropriately abstracted rule to relevant problems. Two points are crucial to this claim.

First, Maria’s developing understanding of the law of large numbers was inseparable from her knowledge of how and where it could be applied. Learning it required her to learn that different circumstances required attunement to different kinds of information and different ways of coordinating it. For example, Maria’s struggles to reason consistently about situations requiring sample outcomes near a population

parameter and those requiring outcomes distant from it revealed her need to acquire means of selecting and coordinating different types of information in different circumstances. According to the demands of each problem, Maria selectively attended to and coordinated individual outcomes of random experiments, expected values of outcomes, ranges of outcomes, and entire sampling distributions. Additionally, Maria initially and spontaneously insisted that she could not apply her rule to a series of spins of a spinner colored 70% blue and 30% green. ("It's not like the coins.") Her ability to see the Spinner Problem as analogous to the Coin Problem depended not only on an adjustment to her understanding of the law of large numbers, but also on a change in her understanding of how spinners behave. Empirical experience with a spinner simulation enabled Maria to recognize that the long-run percentage of blue outcomes on the spinner does indeed *have* an expected value. This analysis calls into question theories suggesting that individuals depend largely on acquiring generalized rules that either are or are not used in objectively relevant situations. In at least some cases, learning a concept, rule, or principle includes learning what kinds of situations are relevant, how such relevance is determined, and how information is differentially selected according to circumstances.

Second, although Maria's ability to state her informal "rule" corresponding to the law of large numbers changed virtually not at all throughout the three sessions, her understanding and use of it changed significantly and depended on an underlying, growing compilation of explanatory concepts and ideas initially evoked only selectively according to problem circumstances. The most striking example of this resulted from the positive role that different problem contexts played in Maria's developing reasoning. The problem involving heights of men walking into a post office to register for the draft elicited only a limited use of statistical reasoning. However, the suggestion to consider the men's heights as being acquired in the context of a campus poll or survey immediately resulted in Maria's description of the relevance of sample size in terms of her ideas of *representativeness* and *accuracy*—ideas that had nowhere before been used by her in any of the five problems she considered. Consequently, through further problem comparison, Maria came to explain the similarity of the problems through a flexible use of ideas revealed through the language of *representativeness*, *accuracy*, *expected value*, and *samples*, which fleshed out her stated *rule*, "the more you do things the closer you get to what's expected." These ideas, once used only selectively according to different circumstances, were ultimately used simultaneously and interchangeably as her understanding grew.

The result of Maria's activities appears not to be a structured, generalized abstraction that she applied to problems having some particular structure, but an increased association and systematization of a set of complementary descriptive and explanatory ideas that could be used flexibly across even non-isomorphic problems. Data from Maria and other students are being used in the construction of a more complete and substantiated account of these processes, which seem consistent with the "knowledge

in pieces” perspective suggested by diSessa (1993) and diSessa and Sherin (1998). In addition to helping to elaborate the notion of transfer, a clearer understanding of what students actually learn in processes of generalization will help educators select learning activities that encourage students to interpret familiar situations in new ways.

The importance of accounting for students' ideas has long been recognized. Ausubel (1968) noted that ". . . the most important single factor influencing learning is what the learner already knows." (p. 68) Curricula in American schools is often broad but shallow (Stigler, Gonzales, Kawanaka, Knoll, & Serrano, 1999; Stigler & Hiebert, 1997), creating an environment that is rife with opportunity for misconceptions to develop and perpetuate. In particular, nearly all of the more traditional textbooks provide little support for building on students' previous knowledge, including identifying and addressing naïve or misconceptions. In particular, the problems with learning statistical concepts have been well-documented from elementary grades through undergraduate statistics classes (Conners, McCown, & Roskos-Ewoldsen, 1998; Fast, 1997; Jones, Langrall, Thornton, & Mongill, 1999; Shaughnessy, 1992). Misconceptions at the middle grades focuses on interpretation and representation of data whereas, at the post secondary level misconceptions have been more prevalent in measures of central tendency and its interpretation. In the present study, we address specifically the ideas related to producing bar graphs from data and using these representations to make conclusions and interpretations from the data.

### Methodology and Results

A sample of 44 preservice elementary teachers and 134 sixth-grade *Connected Mathematics* (Fey, et al.) students were administered an open-ended item from the *Balanced Assessment* (2000). The item, *Vet Club*, was selected as a tool to determine the pervasiveness and persistence of misconceptions in statistical thinking. A rubric for scoring the items was designed to discern students' correct strategies as well as identify specific misconception in graphing and using data to solve a problem. The data are summarized in Table 1.

### Discussion

*Vet Club* elicited several difficulties and misconceptions in statistical thinking. The notion that a particular type of graph was needed to best answer a question about typical data was poorly understood. Interviews indicated that most students constructed

**Table 1.** Data Summary Table

|              | Graphed Zero |     | Misrepresented Axes |     | Type of Graph |     |
|--------------|--------------|-----|---------------------|-----|---------------|-----|
|              | 6th          | UG  | 6th                 | UG  | 6th           | UG  |
| Bar Graph    | 46%          | 31% | 47%                 | 53% | 84            | 32  |
| Circle Graph | 35%          | 33% | NA                  | NA  | 21            | 3   |
| Line Graph   | 31%          | 33% | 34%                 | 33% | 29            | 9   |
| *Histogram   |              |     |                     |     | 67%           | 62% |

Note. \* Bar graphs drawn or referred to as histograms.

their favorite graph with little notion of how to use and interpret it. Student's attributed this naïve conception to previously having constructed graphs as the end-product and not as a means for interpreting data. Similar to the K-12 curriculum, elementary pre-service teachers are seldom provided direct experiences determining the most appropriate graph for data and then interpreting the representation of the data.

## HOW EXPERTS AND NOVICES VISUALLY INSPECT AND THEN INTERPRET GRAPHS

Khalimahtul I. Khalil  
University of Massachusetts  
eena@psych.umass.edu

Clifford Konold  
University of Massachusetts  
konold@srri.umass.edu

This study examines differences in how expert and novice graph-readers explore, compare, and consequently interpret data in a graph comparison task using pairs of stacked-dotplots. Several studies have shown that novices tend not to examine data in graphs as a whole, but view data in smaller sections. This sometimes leads them to draw conclusions about groups that are at odds with what experts might do. Few studies have directly examined what these differences are and how they might result. In this study, we use the Restricted Focus Viewer program to examine whether the way experts vs. novices visually scan graphs are predictive of the types of interpretations they give.

When drawing conclusions about two groups of data, one can view the data in its entirety or concentrate on subsets of the data. Experts tend to view datasets as an entire collection, or aggregate, while novices tend to focus on individual data points or clusters of data with the same values (e.g., Ben-Zvi & Arcavi, 2001; Konold, Robinson, Khalil, Pollatsek, Well, Wing, & Mayr, 2002). From this perspective, an important part of the process of educating students in data analysis involves helping them come to see data in holistic terms. To guide these pedagogical interventions, it would help to know more about how experts vs. novices visually explore data to draw their conclusions. Existing research on this issue is sparse. An eye-tracking study by Embse (1987) using graphs with mathematical functions found that experts (i.e., graduate students and faculty in the mathematics and mathematics education departments) were better at recognizing a target graph compared to novices (i.e., college freshmen in remedial mathematics courses). Embse's study only addressed how well a graph is recognized but not how data in the graph are interpreted.

In this study, we compare how experts and novices behave in a task that requires them to compare data in a pair of stacked-dotplots (a.k.a. frequency bar graphs). Experts were faculty members in the department of psychology while novices were students taking undergraduate psychology classes. Participants examined a variety of graphs showing, for example, daily temperature in two different towns measured on 50 days. The data for the daily temperatures in the towns (Town A and Town B) were plotted in two stacked-dotplots, with the temperature on the x-axis. The participants' task was to determine whether the daily temperature in one town tends to be more or less than the other. Participants visually inspected the stacked-dotplots on a computer monitor using the Restricted Focus Viewer (RFV), a program recently developed as an alternative to conventional eye-tracking apparatus (Blackwell, Jansen, & Marriott,

2000). This program records where and when the participant moves the mouse as they visually inspect the graph. The participant sees only the data located inside a small view window, centered around the cursor of the mouse. This enables us to determine where the participant is looking at any given moment.

We hypothesize that the RFV data will show that novices tend to visually inspect and compare the data using selected vertical slices of the data. For example, they might visually inspect the graphs by drawing the mouse up and down over vertical slices of the graphs and then decide that one town is warmer by comparing the number of days in the two towns in one of these slices (e.g., temperatures above 90 degrees). On the other hand, we expect experts to inspect both distributions systematically by visually scanning each stacked-dotplot horizontally trying to estimate the approximate averages and spreads of each distribution. They will then justify (and perhaps quantify) group differences in terms of these group indices. If it turns out that differences in interpretations are related to different patterns of visual inspection, we would then explore whether structuring how novices visually inspect graphs might help them come to see data more holistically and suggest possible teaching strategies.

## PAIR PROBLEM SOLVING IN PROBABILISTIC SITUATIONS

Hari Koirala

Eastern Connecticut State University, USA  
koiralah@easternct.edu

Fairly large amount of research on collaborative and cooperative learning has been reported in the literature (Kieran & Dreyfus, 1998; Mueller & Fleming, 2001). Much of this research has focused on children working on pairs or small groups and their learning of content and social behaviors. This poster focuses on mathematical work of college graduates when they were asked to solve probability problems in pairs. Two probability problems, transcripts of student discussion, and researcher's interpretation will be included in the poster.

The main task posed in the pair problem solving context was called the head-tail sequence task, wherein participants were asked to determine the most likely sequence of alternatives that might result from flipping a fair coin six times. This was followed by the five-boy task, which asked the participants to determine if a couple has more chance of having a girl if they already have five boys.

Twelve secondary school preservice teachers, who had taken at least 10 mathematics undergraduate courses, including a probability and statistics course, participated in this study. These preservice teachers were paired into six groups based on their responses to a written questionnaire. Each pair consisted of preservice teachers with diverse backgrounds and opinions so as to produce interactions that would help broaden the exploration of students' conceptualization of probability.

In the pair-problem solving, participants were asked to discuss possible solutions to tasks. That is, pairs discussed and attempted to solve tasks together. The investigator observed the pairs' work and made notes. Only in certain circumstances, for example if pairs stopped talking or reached an agreement very quickly, did the investigator provide prompts. The discussions were audiotaped.

Two major findings were noted. First, the participants reported that they felt comfortable in the pair setting because solving the given problems was a shared responsibility of both participants. The preservice teachers were asking questions and providing answers to each other without hesitation, even though the investigator was present during the pair problem solving. Because the participants were sharing their thoughts with each other, the researcher was able to understand their probabilistic thinking without any difficulty.

While attempting to solve probability problems, the preservice teachers used two types of knowledge: Formal probability based on university courses and informal probability based on their everyday intuitions and experiences. Some participants had taken more mathematics and probability courses than the other. However, the number of mathematics courses taken was not necessarily a prominent factor in preservice teachers' attempts to use formal probability during the pair problem solving.

**ANALYZING WRITTEN EXPRESSIONS OF STUDENTS'  
PROBABILISTIC REASONING: DEVELOPMENT  
AND USE OF SCORING RUBRICS**

Eleanor L. Pusey  
elpusey@unity.ncsu.edu

Hollylynne Stohl  
Hollylynne@ncsu.edu

North Carolina State University

Brian E. Townsend  
betd39@mizzou.edu

James E. Tarr  
TarrJ@missouri.edu

University of Missouri

Assessing students' probabilistic reasoning can be a daunting task. In his wish list for future research in stochastics education, Shaughnessy (1992) recognized the lack of reliable assessment tools and called for development of research-based tools to assess students' understanding. This poster will highlight the test items and scoring rubrics that were part of a research study with sixth grade students, the establishment of inter-rater reliability, and analysis of the test scores on pre/post/retention forms.

Stohl and Tarr created the tests using newly developed assessment items, and modified items from prior research (e.g., Piaget & Inhelder, 1975; Fischbein & Schnarch, 1997). The rubrics were based on a synthesis of research in probabilistic reasoning (e.g., Jones, Langrall, Thornton, & Mogill, 1999). The rubrics were developed such that a score on any given item would reflect the student's level of understanding rather than a simple right or wrong evaluation. Such robust descriptions of students' reasoning, coupled with a multi-point scoring system, allows for a deeper and more meaningful analysis of changes in students' thinking over time.

### **Data Sources**

The test data represented one aspect of a larger study (see Stohl & Tarr, this volume). The 23 sixth grade students (14 boys, 9 girls) were in an average-level mathematics class in an urban, southern public middle school. Of the 23 students, six are African-American, two are Hispanic (one ESL), and 15 are Caucasian. Students participated in a 12-day instructional unit on probability that utilized Probability Explorer (Stohl, 1999-2002) simulation software as a primary investigation tool. All students took a pre- and post-test, as well as a retention test given 10 weeks after the completion of the unit.

### **Results**

To establish inter-rater reliability, Pusey and Townsend used scoring rubrics to assign item-level scores on pre- and post-tests (35 items/test) for four students with 97% agreement on the pretests and 91% agreement on the post-tests. The analysis of class mean scores indicates a significant increase from the pre-test mean score to the post-test mean score as evidenced by a paired t-test ( $p=0.00023$ ,  $\alpha=0.05$ ). Duplicate

methods elucidated a significant increase in mean scores from the pre-test to the retention test ( $p=0.01666$ ,  $\alpha=0.05$ ). Item-level mean scores increased significantly from the pre-test to the post-test on 11 of the 35 items and significantly decreased on one question. Between the pre-test and the retention test, nine of the item-level mean scores significantly increased while three items showed a significant decrease. From the post to the retention test, no overall significant difference was found; however, two item-level mean scores significantly increased, while five scores significantly decreased.

Of notable interest to our research group were the significant increases shown on four test items assessing use and understanding of the law of large numbers. A significant increase was demonstrated between pre- and post-test mean scores and the pre- and retention test mean scores on all four items. Since specific interventions using *Probability Explorer* targeted increasing students' understanding of the law of large numbers, the significant test results tend to support the effectiveness of this intervention. Specific items, scoring rubrics, and more detailed analysis will be shared during the poster session.

# **TEACHING WORD PROBLEMS: WHAT HIGH SCHOOL MATHEMATICS TEACHERS VALUE**

Olive Chapman  
University of Calgary  
chapman@ucalgary.ca

Word problems form a central component in the learning and teaching of mathematics. This paper reports on a study of mathematics teachers' thinking in the teaching of word problems with particular focus on what exemplary high school mathematics teachers value in framing their teaching of word problems and what characterizes their teaching of word problems. Case studies of six teachers were conducted. Data collected through interviews and classroom observations were analyzed for attributes of the participants' thinking and actions that were characteristic of their perspective of teaching word problems. The findings provide insights of teachers' way of thinking and classroom behaviors that are important to motivate and engage students meaningfully in doing word problems. There are five student characteristics the teachers intentionally incorporate in their teaching and eight teaching characteristics they value that form the essence of their teaching of word problems. The findings have implications for what we consider and how we work with prospective and experienced teachers to help them to develop/change/enhance their teaching of word problems.

This paper is based on a larger study that is investigating the teaching of mathematical word problems from the perspective of the teacher. The focus here is on the perspective of exemplary high school mathematics teachers, in particular, what they value in framing their teaching of word problems in the classroom, and what characterizes their teaching of word problems.

## **Background and Theoretical Perspective**

Recent reform recommendations in mathematics education, for example, the National Council of Teachers of Mathematics [NCTM] standards and principles (NCTM 1989, 1991, 2000) assign a significant role to problem contexts in developing meaning for mathematics and a problem-solving perspective of teaching and learning mathematics. Implementing such recommendations will necessitate an increase in importance in the use of a range of mathematical word problems, routine or non-routine, in the learning and teaching of mathematics. This is likely to pose increase challenges for both teachers and students. In spite of several studies on problem solving and several theoretical prescriptions on how to become a good problem solver and how to teach problem solving, word problems remain a component of mathematics many students fear and experience increasing difficulty with as they move up the Grades.

Studies on mathematical word problems and problem solving have traditionally focused on the learner to study cognitive and affective factors that aid or hinder his/her performance as a problem solver (e.g., Carpenter, Moser & Debout, 1988; Silver, 1985). Such studies generally identified determinants of problem difficulty,

characteristics of successful and unsuccessful problem solvers, and the relation of meta-cognitive factors to problem solving. They were then used as a basis to design, test and prescribe instruction. In particular, studies on arithmetic and algebraic word problems continue to reflect this trend of focusing on learner-related variables. For example, studies on arithmetic word problems, involving elementary students, (Carey, 1991; Cummings, 1991; Debout, 1990; Feinberg, 1988; Fuson & Willis, 1989; Lewis & Mayer, 1987; Sowder, 1988) have looked at the mathematical and linguistic structure of these problems in relation to the children's performance; factors that affect the difficulty of the problem for children; strategies and methods children use; and the errors children make in their solutions. More recently, Verschaffel, Greer and DeCorte (2000) have looked at students' suspension of sense making in doing word problems. They pointed out that after several years of traditional mathematics instruction, students have developed a tendency to reduce word-problem solving to selecting what they take to be the correct arithmetic operation with the numbers given in the problem, without seriously taking into account their common-sense knowledge and realistic considerations about the problem context. A similar situation has existed for studies on algebraic word problems, involving high school students, where, for example, the focus has been on students' errors and methods in the translation process (Clement, 1982; Crowley, Thomas & Tall, 1994; Kaput & Sims-Knight, 1983; MacGregor & Stacey, 1993; Wollman, 1983). Reed (1999) provides a current overview of studies of both arithmetic and algebraic word problems.

Given the focus on the learner, studies on mathematical problem solving have generally ignored or trivialized the classroom teacher. Even in cases where instruction was considered, the studies were still biased towards the learner in that they generally focused on the effectiveness (in terms of students' performance) of instructional methods designed by the researcher and administered under experimental conditions. Thus, while these studies have enhanced our understanding of important issues associated with the learning of word problems, they offer very little on the teacher. But this situation was eventually considered by some researchers to be a significant limitation in understanding and improving the teaching, and consequently, the learning of problem solving. For example, such lack of research on the teacher in problem-solving instruction has been proposed as a significant limitation in understanding and improving the teaching of problem solving (Lester, 1994; 1985). The initial concern was that "we will make no progress toward developing practical guidelines for mathematics teachers to follow until we are able to make explicit that knowledge about teaching that good teachers have internalized and made 'second nature'" (Lester, 1985, p.56). The study in this paper is intended to make explicit aspects of teacher thinking and classroom behavior that exemplary high school teachers consider important in framing their teaching of word problems in the classroom.

The study, then, is framed in the theoretical perspective of teacher thinking in which teachers are viewed as creating their own meaning to make sense of their teach-

ing, i.e., a constructivist orientation of knowledge construction. Research on teacher thinking is well established (Elbaz, 1991; Fenstermacher, 1994; Grossman, 1990). The importance of researching the teacher is associated with the view that teachers are the determining factor of how the curriculum, mathematics in this case, is taught. Within this humanistic view of the teacher, the teacher's thinking is valued as a basis for understanding her/his classroom behaviors, in particular, and teaching, in general. This validates the importance to learn from teachers what they do and how they make sense of what they do (i.e., their perspective) in the context of the classroom.

In recent years, there has been increased focus on researching the mathematics teacher. Thus, there is a growing body of literature on mathematics teachers' content knowledge, beliefs, conceptions, classroom practices, learning, professional development and change (e.g., Lampert & Ball, 1998; Chapman, 1997; Fennema & Nelson, 1997; Lloyd & Wilson, 1998; Schifter, 1998; Thompson, 1992; Tzur, Simon, Heinz & Kinzel, 2001). These studies have provided us with insights on, for example, the relationship between beliefs and teaching, deficiencies in teachers' content knowledge, and the challenges of teacher education and change. The literature also suggests that mathematics teachers' beliefs and conceptions about mathematics and its teaching and learning are significantly related to their teaching. As Ernest (1989) explained, in relation to mathematics teachers, it is the teachers' mental or espoused models of teaching and learning that are transformed into classroom practices. This view of the teacher suggests that the teaching of word problems in a classroom context could depend on the teachers' underlying beliefs and conceptions framing it, or, more generally, on the teacher's thinking. However, ongoing research to understand the high school mathematics classroom from the teacher's perspective, in general, and explicitly dealing with the teaching of word problems, in particular, is important as we try to reform the teaching of mathematics. In this study, the teachers' perspective includes their conceptions, their intentions, what they value and personal meaning.

### **Research Method**

The study is framed in a naturalistic inquiry perspective that facilitates a phenomenological context to interpret one's thinking and behavior (Taylor & Bogdan, 1998). The participants were six experienced high school teachers (4 females, 2 males, 16-30 years experience), considered to be excellent teachers in their school system. Their students have consistently scored very high on their provincial standardized examination that has a growing emphasis on problem solving following the NCTM standards. They had positive attitudes to teaching mathematics, in general, and word problems, in particular. They have been involved in making presentations at mathematics teachers' conferences and/or leading professional development workshops, although not specifically related to teaching word problems.

The main sources of data for the study were interviews and classroom observations. The interviews were open-ended to give the participants an opportunity to talk

freely and in an unprompted way about their own understandings of teaching word problems. They were also partly framed in a narrative perspective to allow the teachers to describe their experiences as actual phenomena. This produced stories of actual events that embodied the meaning of the participants' behavior. The interviews dealt with the participants' thinking in three contexts: past, present and future. The past dealt with their past experiences with word problems as both students and teachers focusing on teacher and student presage characteristics, task features, and contextual conditions. The present dealt with their current practice with particular emphasis on classroom processes, planning and intentions. The future dealt with expectations, e.g., possible changes due to personal or external factors, and, "if ... what" scenarios.

Classroom observations focused on the participants' actual instructional behaviors during lessons involving word problems. Special attention was given to what the teachers and students did during instruction and how their actions interacted. Complete units involving word problems were observed. Post-observation discussions with the participants focused on clarifying their thinking in relation to their actions. All interviews and discussions were audio taped and transcribed. The data were thoroughly reviewed by the researcher and two research assistants working independently to identify attributes (e.g., recurring conceptions/beliefs, intentions, judgements) of the participants' thinking and actions that were characteristic of their perspective of teaching word problems. These attributes were grouped into themes. Both attributes and themes were validated by comparison of findings by the three reviewers and triangulation of findings from interviews and classroom observations.

### **Findings**

The teachers' thinking about mathematics, word problems, problem solving and the teaching and learning of word problems played a significant role in framing their teaching of word problems in a classroom context. For all of the participants, for the most part, there was consistency between their thinking about teaching word problems and what they actually did in the classroom. There was evidence of some of them, over their careers, having consistently worked at resolving significant conflicts they were aware of between their beliefs about mathematics and their teaching that could help to explain this consistency (Chapman, in press).

The thinking of the participants identified as exemplary teachers reflected a broader range of characteristics and more depth in conceptualizing word problems and teaching word problems than that of the traditional teachers who were participants in the larger study. Each participant was unique in her/his thinking and behavior and there were differences in how each characterized her/his conceptions and in her/his classroom actions. However, as exemplary teachers, there were many similarities conceptually resulting from a common underlying theme in their thinking and behavior that reflected a humanistic view of mathematics, word problems and problem solving and a student-centered view of learning and teaching. All of the teachers thought that,

and a student-centered view of learning and teaching. All of the teachers thought that, as one of them put it, “it does not work to just stand up in front and say, okay, if you see a question like this you do this, this, and this, and this is how you solve it.” They also acknowledged that the students who came into their classes generally had a fear of word problems, but they believed that this fear could be significantly reduced if the situation was set up to facilitate this. Thus their teaching was characterized by several factors that were intended to enhance students’ affective relationship to word problems and cognitive perspective of dealing with word problems. A detailed discussion of all the key aspects of the teachers’ thinking and behaviors cannot be adequately provided here, so the focus will be on outlining some of the key factors which reflect what the teachers valued in framing how they created and facilitated effective/meaningful instruction in the teaching of word problems.

Although other factors (e.g., conceptions of mathematics, word problems, and problem solving) played a role, the teachers considered the students as the primary basis of determining what their teaching of word problems should look like. Their student-centered approach to teaching was directly related to the importance they placed on the following five student characteristics they intentionally incorporated or tried to achieve in their teaching: (i) Real life activities/experiences: This was used to make the word problems relevant or interesting for students. (ii) Ability: This was used to determine how and when to integrate difficult problems with easier ones. (iii) Affective factors, e.g., fear, motivation, sense of success, confidence: This formed a basis for the teachers’ goal to get students motivated to move from fear to confidence and success. As one teacher explained: “The teacher should also help students develop a feeling of success, to experience success and to be confident in their ability to do word problems and to see them as fun.” (iv) Autonomy: This was used to give students ownership of their learning, e.g., selecting word problems and solution processes that they found to be meaningful. (v) Understanding: This was interpreted as allowing students to construct their own meaning, e.g., their interpretations of word problems and solution processes. These characteristics are not elaborated on here, but are reflected in the description of the teaching characteristics that follow.

The exemplary teachers’ thinking and classroom behaviors revealed eight characteristics they valued that formed the essence of their teaching of word problems. While they are all listed here, they are described with varying depth that is reflective of the constraint on space and not importance of each characteristic. All quotes in the description of each characteristic are from the data.

- (i) **Triologue Relationship:** The general structure of the teachers’ teaching was a triangular relationship between the teacher, students and word problem, i.e., there was a triologue in which both teacher and students could learn something from each other. In this model (Chapman, forthcoming), the teacher specifies the problem for him/herself based on his/her interpretation of it and is speci-

imposing this interpretation on students, the teacher allows them, individually and/or as small groups, to specify the problem for themselves based on their interpretations of it and to be specified by what is allowed by the context of the problem. Finally, by listening to, observing and strategically intervening in the students' relationship with the problem, the teacher allows him/herself to be specified by the students and the students to be specified by the teacher in an open-ended way based on the teacher being flexible and open to a range of justifiable possibilities for solution to the problem. *Specified* is being used in a phenomenological context and relates to how a phenomena is experienced or provides options for it to be experienced.

- (ii) **Connected-Separate Knowing:** The teachers often supported students working from a form of *connected-knowing perspective* to a *separate-knowing perspective* (Chapman, forthcoming). In the former, students were allowed to focus on the social context of the problem by trying to experience the problem, to relate it to their personal world. The teachers viewed this as being motivational, so to facilitate it, they preferred to work with problem situations that had "realistic value for the students." When such problems were not readily available, e.g., in case of traditional textbook problems, the teachers encouraged students to make fun of "stupid problems" and joke about the cover story of the problem, to revise problem situations/context, and to construct problems about things/situations that they found interesting to share with each other. For example, as one teacher explained: "If they say 'it's a stupid problem', I say, 'Ok, so how would you write this problem? You write the problem so it has more meaning for you instead of using some name that you don't know in the problem.'" The teachers treated this process of personalizing the problem context as both a way of knowing and a means of motivating students. They viewed it as paving the way for students to move beyond surface features of the problem and to engage in separate knowing, i.e., focusing on the mathematical context of the problem by suppressing the self in relation to the social context of the problem and taking an impersonal stance toward the problem. For example, students were required to reflect on the problem to see the structure of it and how they could generalize it. Students were also required to reflect on the solution to allow them to see the structure of it and the circumstances under which it would work and not work. The goal during separate knowing was on developing and applying some model for dealing with problems of similar mathematical context.
- (iii) **Integration:** The teachers preferred "integrating the word problems throughout the course and not treating them as something separate or as an isolated topic of mathematics" ... "[treating them] as something that is ongoing and not a particular unit in mathematics." For e.g., the teachers would use word prob-

particular unit in mathematics.” For e.g., the teachers would use word problems to start, develop and/or end each topic.

- (iv) Collaboration: The teachers emphasized collaboration in developing the solution process when word problems/new topics were introduced. This was done through whole-class discussions and small-group work. Whole-class discussion was always accompanied with small-group work, which could occur before and/or after it. During the whole-class discussions, the teachers’ focused on “drawing on the students’ experiences and perspectives”. There were various ways in which the group-whole-class combination unfolded depending on the teacher, students and topic. In one scenario, the teacher would put students in groups at the beginning of the year and give them some word problems “to look at and to see what they come up with on their own”. This is followed by a whole-class discussion where the students have to explain and discuss their interpretation of the problem and their solutions, whether completed or not, and reflecting on their approach. As this teacher explained, they have to address, “What did we [the students] do? What tools did we use? Why did it work or not work? Is there a better way?”

Collaboration among students was also encouraged, with individual work, for practicing problems. The teachers viewed collaboration among students as being important in helping them “to understand that there are others who are experiencing the same difficulties as themselves, who can have a different perspective that they can learn from, and they can bring something to the problem situation that others may not have thought of.” Thus, in general, the teachers viewed this shared experience as playing an important role in motivating students and giving them confidence to work individually.

- (v) Questioning: The teachers used a questioning approach to facilitate whole-class discussions or to intervene in the groups. Questioning was in the form of questions and prompts that required students to engage in mathematical thinking and to share their thinking – “their experiences and perspectives.”
- (vi) Writing: The teachers gave students opportunities to write as a way of learning how to approach word problems. For example, students got to construct word problems and were encouraged to write about their thinking when they solved a word problem, particularly in situations where they were encountering difficulties getting started or getting to a resolution of the problem. As one teacher explained, when they were stuck, her students were required to write about “how they started the problem and how this didn’t work and that didn’t work. ... [This allows them ]to describe their process so they can see that they are on a journey, if you will, to find the solution and sometimes the journey does not go right but at least they’ve started and done something. They should begin writing whatever they are thinking of immediately so that they don’t

leave blank pieces of paper and they are not afraid to try different kinds of things.”

- (vii) Choice/ Flexibility: The teachers gave students the choice to use “whatever mathematical tools they are made aware that they have to solve the problems.” As another teacher said, “it doesn’t make any difference what kind of methodology they use as long as it is logical and they can explain it and let other people understand it.” Another noted, “If we mark them on what they can show us and not just the right answer or the wrong answer, we can develop that confidence in students.” Students were also given choices on tests and assignments. For example, with practice problems, some teachers sometimes assigned to students 5 or 6 “longer problems” during the class or for homework, but required that “they only turn in the ones that they think were their two best solutions so that they have some choice.” Sometimes on tests, they were also given a choice.
- (viii) Assessment Disclosure: The teachers made students “aware of how these problems will be assessed”. For example, they helped students to understand how they were going to be graded, “whether it is by use of rubrics or something else”. One way this was done was by “looking at examples of solutions that ranged from excellent to really terrible” in terms of how they were presented and not “the correct way” and discussing them from an assessment perspective.

The above eight teaching characteristics were reflected in all of the teachers’ thinking and classrooms, but there were variations in how they were articulated and lived in the classroom. Thus, each teacher was unique in how these teaching characteristics unfolded in her/his classroom. For example, each teacher weaved his/her classroom activities in teaching algebraic word problems with systems of linear equations with his/her own personal touch. The following is an example of one of the teachers’ approach for a unit on systems of equations. The whole unit, as opposed to a single class, is presented because of the way the word problems are integrated throughout the unit as an integral part of it. It is also written in a way to reflect the teacher’s ongoing use of the approach.

One week prior to starting and discussing the topic in class, the teacher asks the students to collect pictures of graphs that intersect from any source other than a mathematics textbook. The graphs do not necessarily have to be lines. They can be any graphs that intersect. But they should represent actual real-life situations. These pictures are considered to be related to word problems because there is a cover story associated with them.

For the first class of the unit on systems of linear equations, students bring their pictures and share them in a whole-class setting. They spend the whole class looking at

and discussing everyone's picture. Each student shows his/her picture and talks about what the graph represents, the significance of the graph, what it means when graphs intersect, what the intersection shows, why the intersection is important, why anyone would want to find the intersection in the first place. The graphs the students collect are usually about business/economics and physical science situations. Economics situations tend to be dominant because, according to the teacher, they are talking about money with which the students seem to relate more meaningfully. For homework, the teacher gives the students a word problem that requires them to determine, if they have a part-time job, whether it is better to have a fixed hourly rate or a fixed weekly salary plus commission over a specified time period. The students are to try and solve the problem in any way they could.

The second class starts with sharing and discussion of the students' solutions to the homework problem. The teacher poses questions about how the graphical approach was or can be used to solve the problem, how the point of intersection or break-even point was or is useful to the analysis and solution of the problem, and the relevance of solving systems of two linear equations to the students' real-life experiences. The teacher then points out that since they [teacher and students] have decided that it is important to look at where graphs intersect, then they are going to particularly study lines, linear equations, and their intersection. She asks students to return to the graphs they had collected and, for graphs involving two intersecting straight lines, to work in groups to set up the equations for each set of lines using data they read off the graphs. Following this, the teacher facilitates a whole-class discussion of the meaning of the algebraic representations in the context of the applications and why they are useful. In particular, the class discusses the usefulness of an algebraic approach instead of a graphical approach to find the point of intersection. The students, working in groups, then use their graphing calculators to plot examples of special cases of systems of two linear equations that the teacher writes on the chalkboard, e.g.,

$$x + y = 4 \text{ and } 2x + 2y = 8$$

$$2x + y = 3 \text{ and } 2x + y = 5.$$

These are intended for students to investigate and discuss other relationships between two equations, e.g., "what happens if they [the lines] do not intersect? What does it mean if one line is on top of another?" The investigation is followed by whole-class sharing and discussion of their findings. To end the class, the teacher requests that students form groups and each group is assigned a different method to solve systems of equations as required by the curriculum. As she explained, "One group looks at solving these systems of equations graphically, another group looks at solving them using an addition method or a subtraction method [i.e., elimination method] and the third group looks at solving them by substitution."

For the next two classes, students work in their groups investigating the particular solution pattern for the one method to solve a system of two linear equations they are

assigned. The goal is for the group to study solved examples by themselves to try to understand the structure of the method and be able to teach it to others. Thus the students are developing their own versions of what the methods are about. The teacher circulates, observes and intervenes with questions or a counter example to make students think about any limitations she sees in the way they understand the method, e.g., "Would that work for ...?" Students are left to resolve all conflicts for themselves. The teacher assigns exercises to each group to use to test the understanding they construct of the method. The exercise contains equations with coefficients and constants that are all whole numbers, all integers, all rational numbers or some combination of these numbers. For homework, the teacher asks the students to make up a word problem that can be solved with the method they explored in class. The teacher rewards students for creativity, so reproducing problems from a textbook is discouraged and not valued. To end the class, the students have to plan how to teach their approach to others in a way that is interesting and will help them to understand it.

In the fifth class, each group teaches the method they explored to the other groups. This is done by representatives from the teaching group going to each of the other groups to explain to them what they had done in their own group and teach them the method. They are to also make a case that their method is the most efficient. Again, the teacher circulates, observes and intervenes with a counter example to make students think about any limitations she sees in the way they understand the method. Students are left to resolve all conflicts for themselves. For homework, the students are assigned to select and complete practice exercises from those exercises assigned to the groups for each method that have not been completed in class before it ended. The students also are assigned "to bring in real-world word problems that they find elsewhere, other than the textbook, to talk about how they use or can solve systems." For example, "one of the kids brought in internet prices, so they were looking at going with AOL or someone else, and so they brought in a graph that showed these two particular companies and where the break-even point would be so that it wouldn't make any difference which one they had." The teacher assigns 20 percent of their unit mark for "finding a pertinent problem that uses systems and solving it".

In the next two classes, each group works on word problems the teacher selects from the textbook and from what the students have developed. The teacher provides open-ended hints whenever students are stuck but never tells them explicitly how to do anything. Each group then "comes to the front of the class with a different problem that they want to share with the class." Any problems no one in the class is able to do, even after receiving the hints, are identified at the end of the class. Students are asked to continue to think about them for homework.

In the eighth class, the unresolved problems are dealt with in a whole-class discussion in which the teacher poses questions that help the students to arrive at a solution collectively. For the remainder of the class, the teacher facilitates a whole-class discus-

sion on informal extensions of the topic posing questions like, "what if there are three equations instead of two?"

Finally, in the last class of the unit, the teacher gives the students a written test on the topic. For word problems on the test, the teacher includes the final answers. Thus, there is no mark for the final answer, reinforcing the importance of understanding and explaining [through writing] the process.

This teacher's approach is far removed from the traditional classroom approach to dealing with systems of equations, and the most innovative of all of the participants' approaches. But all of the teachers taught in a way that reflects current reform recommendations in mathematics education. These teachers, at the beginning of a semester, explicitly worked at creating the tone in their classroom to allow students to work in this way. In general, their teaching had positive effects on students' attitude and learning of word problems.

### Conclusion

The study shows that for these teachers, effective teaching of word problems is more complicated than walking students through examples of solution patterns or heuristics. Instead, it is a particular interplay between teacher, student and word problem that is orchestrated by the teacher based on what the teacher values. The findings provide evidence for teachers that the teaching of high school mathematics does not have to be dominated by telling. But a relativistic view of mathematics teaching based on students' understanding and motivation is desirable and achievable. The findings also reveals specific factors, from real classrooms, of teachers' way of thinking and classroom behaviors that are important to motivate and engage students meaningfully and effectively in doing word problems. This has implications for what we consider and how we work with prospective and experienced teachers in order to help them to develop/change/enhance their teaching of word problems.

# **PRESERVICE SECONDARY MATHEMATICS TEACHERS' MODELING STRATEGIES TO SOLVE PROBLEMATIC SUBTRACTION AND ADDITION WORD PROBLEMS INVOLVING ORDINAL NUMBERS AND THEIR INTERPRETATIONS OF SOLUTIONS**

José N. Contreras  
The University of Southern Mississippi  
Jose.Contreras@usm.edu

In this study I examined 19 preservice secondary mathematics teachers' solution processes to word problems for which the subtraction or addition of the two given numbers yields 1 more or 1 less than the correct solution. Among the aspects of their solution processes that were examined are: the modeling strategies, the type of errors, and the interpretations of the solutions produced by the procedure. It was found that about 87% of the solution processes to such problems contained formal strategies while about 13% contained counting strategies. It was also found that about 61% of the responses contained errors of which 91% were  $\pm 1$  errors. That is, errors due to the interpretation that the answer provided by the addition or subtraction of the two given numbers is the solution to the problem. It is argued that some incorrect interpretations were due, at least in part, to a lack of understanding of the connection between the enumeration process needed to obtain the solution to a problem and the answer provided by the addition or subtraction of the two given numbers.

Current reform documents such as *Principles and Standards for School Mathematics* (National Council of Teachers of Mathematics, 2000) call for students to learn to solve non-routine problems and to establish connections between mathematical ideas and real-world situations. Special types of non-routine problems include problematic story problems involving arithmetic operations. For the purpose of this article, a problematic story problem is a problem for which the result provided by the mathematical operation or procedure with the numbers given in the problem statement does not necessarily represent the solution to the problem. Research studies (e.g., Cai & Silver, 1995; Contreras, 2001; Greer, 1993, 1997; Nesher, 1980; Reusser & Stebler, 1997; Silver, Shapiro, & Deutsch, 1993; Verschaffel & De Corte, 1997; Verschaffel, De Corte, & Lasure, 1994; Verschaffel, De Corte, & Vierstraete, 1999; Verschaffel, Greer, & De Corte, 2000) suggest that students tend to approach problematic story problems mechanically or superficially without paying attention to the realistic considerations of the situational context of the problem or to their modeling assumptions. Some examples of problematic word problems used in some of these studies are the following:

- (a) What will be the temperature of water in a container if you pour 1 l of water at 80° and 1 l of water of 40° into it? (Nesher, 1980)
- (b) John's best time to run 100 m is 17 sec. How long will it take to run 1 km? (Greer, 1993)

- (c) The Clearview Little League is going to a Pirates game. There are 540 people, including players, coaches, and parents. They will travel by bus, and each bus holds 40 people. How many buses will they need to get to the game? (Silver, Shapiro, & Deutsch, 1993)
- (d) Lida is making muffins that require  $\frac{3}{8}$  of a cup of flour each. If she has 10 cups of flour, how many muffins can Lida make? (Contreras & Martínez, 2001)
- (e) In September 1995 the city's youth orchestra had its first concert. In what year will the orchestra have its fifth concert if it holds one concert every year? (Verschaffel, De Corte, & Vierstraete, 1999)

Verschaffel, De Corte, and Lasure (1994) used, among others, items a) and b) in their study involving 75 fifth graders in Flanders. Their analysis revealed that only 7 (9%) students provided a realistic and correct response to the first problem and only 2 (3%) provided a response to the second problem that was based on realistic considerations. Silver, Shapiro, and Deutsch (1993) investigated 195 middle grade students' solution processes and their interpretations of solutions to the third problem. They reported that about 22% of the students correctly performed an appropriate procedure but provided an incorrect solution without explicit interpretation. Most of the students interpreted the result of the division (e.g., 13 or 13 with another number) as the number of needed buses. In their study, Contreras and Martínez (2001) examined 68 preservice elementary teachers' solution processes and realistic reactions to the fourth problem. They reported that only 19 (28%) of the participants' responses contained a realistic solution to the problem. They also reported that none of the participants made any comments about the problematic nature of the problem. Finally, Verschaffel, De Corte, and Vierstraete (1999) examined 199 upper elementary school pupil's difficulties in modeling and solving problematic additive word problems involving ordinal numbers. They administered the subjects a paper-and-pencil test consisting of 17 word problems, nine of which were experimental items and eight buffer items. Three of the nine experimental items can be solved by a simple addition or subtraction of the two given numbers. An example of this type of problems is "In January 1995 a youth orchestra was set up in our city. In what year will the orchestra have its fifth anniversary?" The solution to the other six items is either 1 more or 1 less than the answer provided by the addition or subtraction of the two given numbers. An example of this kind of problems is problem e) stated above. Verschaffel, De Corte, and Vierstraete found that the percentage of correct responses for each of the six problematic word problems was less than 25%. They reported that 83% of the errors made on these problems were  $\pm 1$  errors. That is, most of the pupils' errors were due to their interpretation that the addition or subtraction of the two given numbers provides the solution to the problem.

As argued by Verschaffel, De Corte, and Vierstraete (1999), a problem with all of these investigations and others reported in the literature is that they have involved

elementary or secondary students and, thus, a possible generalization to college students and, in particular, to prospective secondary mathematics teachers has not been established empirically. Second, since prospective secondary mathematics teachers are a more mature population from a psychological and mathematical point of view, it would be worthwhile to analyze their solution processes to examine the strategies, errors, and interpretations when solving problematic word problems. Finally, it is important to document, examine, and understand prospective secondary mathematics teachers' strategies, errors, and interpretations when modeling and solving problematic word problems because the teacher is one of the major agents in the classroom. It is the teacher who designs, adapts, or implements the instructional activities. If we want students to model and solve problematic word problems by taking into account the realistic considerations embedded in the problem situation, then it is necessary that the teachers themselves have the experience, disposition, and ability to model and solve such problems realistically. The purpose of this study is to extend Verschaffel, De Corte, and Vierstraete's (1999) investigation. First, I examine prospective secondary mathematics teachers' modeling strategies to solve problematic subtraction and addition word problems involving ordinal numbers. Second, I examine the type of errors, if any, that secondary teachers make when solving such problems. Finally, I examine their interpretations of the solutions provided by the procedure or mathematical model.

### **Theoretical Framework**

Aspects of reality can be represented by mathematical means. This process of representation is called mathematical modeling. Some physical or real-world problems can also be solved by means of a process of mathematical modeling such as the one depicted in Figure 1 that was proposed by Silver, Shapiro, and Deutsch (1993). There are other models described in the literature (e.g., Verschaffel, Greer, & De Corte, 2000) but Silver, Shapiro and Deutsch's model is appropriate for the present study.

According to Silver, Shapiro, and Deutsch's model, the (simplified) process of mathematical modeling involves four phases. The first phase consists of understanding the structure of the mathematical problem embedded in the story text. During this phase we need to understand the given information, the unknown information, extraneous information, and realistic considerations embedded in the situational context. The second phase consists of constructing a mathematical model or selecting an appropriate procedure, operation, or algorithm whose result will lead us to the solution of the word problem. During the third phase we execute the procedure or algorithm. Finally, we interpret the result provided by the mathematical model or procedure in terms of the realistic context embedded in the story text of the word problem or in terms of the real-world story situation. It is during the fourth phase that we focus on the meaning of the answer produced by the mathematical procedure or computation. Students' responses to problematic word problems could include realistic or correct

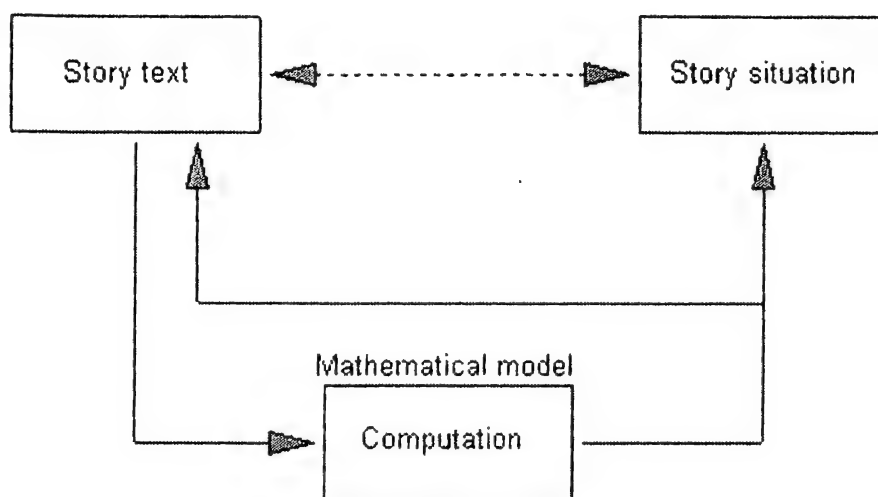

Figure 1. Silver et al.'s (1993) referential-and-semantic-processing model for successful solutions.

solutions if they select an appropriate procedure or operation and understand or pay more attention to the meaning of the result produced by the mathematical model.

Silver, Shapiro, and Deutsch's model implies that there are three main potential sources of errors when solving word problems: lack of understanding of the problem, which is suggested when an inappropriate procedure is chosen, incorrect execution of procedures, and incorrect interpretation of the answer produced by the mathematical model or procedure. In their study of the division problem involving remainders stated above, Silver, Shapiro, and Deutsch (1993) found that most of the students' responses, 91% in fact, contained an appropriate procedure (e.g., long division, repeated multiples, repeated addition, etc.) but only 61% of the students who selected an appropriate procedure performed it flawlessly (about 56% of the total number of students). These researchers reported that only 43% of the total number of students provided the correct answer of 14 to the problem but that some of them gave inappropriate interpretations. For example, one student wrote "14 buses because there's leftover people and if you add a zero you will get 130 buses so you sort of had to estimate. Are we allowed to add zeros?" (p. 124-125). About 55% of the students did not get the correct answer because they either failed to interpret the answer produced by the division computation or made computational mistakes that could have been detected if students had interpreted their solutions correctly. The researchers proposed the model exhibited in Figure 2 as a schematic representation of an unsuccessful solution. That is, some students failed to get the correct solution to the problem because they did not map the result produced by the mathematical model (in this case, a division) back to either the story text or the real-world story situation.

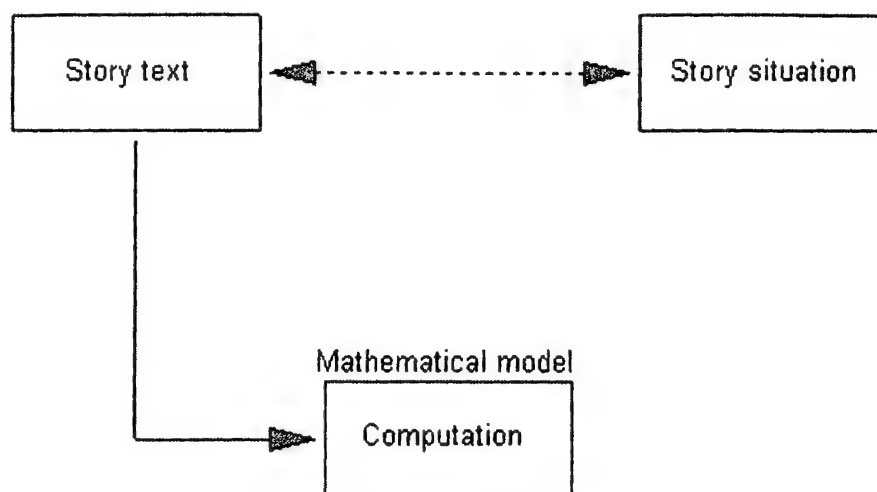

Figure 2. Silver et al.'s (1993) referential-and-semantic-processing model for unsuccessful solutions.

### Methods and Sources of Evidence

A paper-and-pencil test was administered to 19 prospective secondary mathematics teachers from three required mathematics classes. Fifteen students were female and four male. All students except one were mathematics majors. At our institution, teachers seeking 7-12 certification in mathematics are required to complete a mathematics major. The non-mathematics major was seeking a supplementary endorsement in mathematics. The written directions included asking students to show work to support their responses. Calculators were not allowed. The test contained nine experimental items and some buffer items. The experimental items were adapted from Verschaffel, De Corte, and Vierstraete's (1999) test. Table 1 displays the nine experimental items. All the experimental items were addition and subtraction word problems involving ordinal numbers. Three of the nine experimental items can be solved by the straightforward addition or subtraction of the two numbers given in the problem statement. The solution of the other six items is 1 more or 1 less than the answer produced by the subtraction or addition of the given numbers.

A difference from some previous research, where the word problems have been designed in an ad hoc way, Verschaffel, De Corte, and Vierstraete's were based on a taxonomy of the possible modeling complexities. The nine experimental items differ in terms of two dimensions: (a) the nature of the underlying mathematical structure and (b) the nature of the unknown information. We can distinguish three categories of problems (Types I, II, and III) based on mathematical structure. The solution of Type I problems can be obtained by adding or subtracting the two numbers given in the problem. The solution of Type II and Type III problems is 1 more or 1 less than the answer produced by the addition or subtraction of the two given numbers. Types

**Table 1.** The Nine Experimental Items

| Type  | Item   | Required operation(s)* |
|-------|--|------------------------|
| I-L   | 1. In January 1985 a youth orchestra was set up in our city. In what year will the orchestra have its twenty fifth anniversary?  | $S + D$                |
| I-D   | 2. Our youth club was set up in September 15, 1970. I became a member in September 15, 1999. How many years had the club already existed when I became a member?   | $L - S$                |
| I-S   | 3. In March 2000 it had been 34 years since our school had held its first annual school party. In what year was the school party held for the first time?  | $L - D$                |
| II-L  | 4. In September 1975 the city's youth orchestra had its first concert. In what year will the orchestra have its fiftieth concert if it holds one concert every year?   | $(S + D) - 1$          |
| II-D  | 5. Last October (2001) I participated for the first time in the great city running race that is held every year. This race was held for the first time in October 1959. How many times has the race been held?   | $(L - S) + 1$          |
| II-S  | 6. In November 1994 the twenty fifth annual school party took place. In what year was the school party held for the first time?  | $(L - D) + 1$          |
| III-L | 7. There was a summer market in our city every summer from 1950 up through 1969. Since then the summer market was cancelled 30 consecutive times. In what year did the summer market restart?  | $(S + D) + 1$          |
| III-D | 8. For a long time the city held a fireworks display every year on the last day of the October festival. In October 1982 we had our last fireworks, and thereafter there was no fireworks display. In October 1999 they restarted the tradition of the annual fireworks display. How many years did we miss the fireworks? | $(L - S) - 1$          |
| III-S | 9. In December 1999 our sports club held its annual election for its officers. Because of a lack of candidates, there had not been elections for the 23 years preceding 1999. Prior to this election, in what year did the last election occur?  | $(L - D) - 1$          |

\* L = larger ordinal number

S = smaller ordinal number,

D = difference between the two ordinal numbers.

II and III problems differ in the nature of the enumeration process used to obtain the solution. For Type II problems, the enumeration process begins with the smaller number or the larger number. For Type III problems, the enumeration process needed to obtain the solution does not include neither the smaller nor the larger number. With respect to the nature of the unknown information, three categories of problems can be distinguished: (a) problems for which the larger number is unknown (Type L problems), (b) problems in which the smaller number is unknown (Type S problems), and (c) problems for which the difference between the two ordinal numbers is unknown (Type D problems). Combining the two dimensions in which the problems differ, we can obtain nine possible different types of addition and subtraction word problems involving ordinal numbers.

The main source of data was the written responses provided by the prospective secondary mathematics teachers. I recognize that written responses have some limitations as compared to verbal protocols. However, several researchers (e.g., Hall, Kibler, Wenger, & Truxaw, 1989) have validated the use of written responses to infer cognitive processes. In fact, I did not have any difficulty to determine the strategies that the prospective secondary mathematics teachers used to solve the problems. Nevertheless, I conducted interviews with the students to gain a deeper understanding of the thinking and reasoning that students used to solve the problematic word problems.

### Analysis and Results

Students' written responses were analyzed with respect to four aspects of the process of mathematical modeling represented in Silver, Shapiro, and Deutsch's (1993) model: (a) the strategy, procedure, and operation used by the students to solve each problem, (b) the execution of procedures, (c) the solution to each problem, and (d) the (implicit or explicit) interpretation of the result produced by the mathematical model or procedure. I also conducted an error analysis to determine the type of errors that prevented students from obtaining the correct solution to each experimental item. The students produced a total of 171 responses (57 responses to the non-problematic experimental items and 114 responses to the problematic experimental items). The strategies used by the students were categorized as formal strategies (addition or subtraction of the two numbers given in the problem), or informal (e.g., counting). A total of 55 (96%) responses to the non-problematic items contained a formal strategy, one (2%) contained a counting technique, and another one (2%) contained solving a similar simpler problem. On the other hand, 99 (87%) responses to the problematic items contained a formal strategy and the remaining 15 (13%) contained counting techniques. Overall, 154 (90%) responses contained a formal strategy, 16 (9%) contained counting techniques, and only one (1%) involved solving a similar simpler problem. Students' responses were also analyzed to determine the appropriateness of the procedure, algorithm or operation used to solve the problems. A procedure was judged as appropriate if it could lead to the correct solution or as inappropriate otherwise. Not surprisingly, all students used appropriate procedures. With respect to the execution of procedures,

students performed 162 (95%) procedures correctly. Regarding the solutions to the experimental problems, 85 (50%) of the responses contained correct solutions. Specifically, 41 (72%) of the 57 responses of the non-problematic word problems contained correct solutions and only 44 (39%) of the 114 solutions to the six problematic word problems were correct. Considering that all subjects but one were mathematics majors, the percentage of correct solutions was much lower than I expect it. The percentage of correct solutions to each experimental item is exhibited in Table 2.

As we can see from Table 2, the percentage of correct solutions to the problematic word problems varied from 32% (problems 4 and 6) to 47% (problem 8). Even though the participants have probably had extensive experience with routine arithmetic word problems, I was expecting that this sample of prospective secondary mathematics teachers would perform much better on the six problematic word problems because all but one were math majors. Since a high percentage of the procedures was executed correctly, I conducted an error analysis to find out what prevented the prospective teachers from getting the correct answer on the problematic word problems and to further our understanding of students' solution processes. Based on previous research, I predicted that most of the students' errors were  $\pm 1$  errors. The results are displayed in Table 3.

The error analysis confirmed my prediction. As shown in Table 3, a high percentage of errors for each problematic item was  $\pm 1$  errors. Overall, the percentage of  $\pm 1$  errors made on the problematic items was 91%. A total of 64 (56%) of the solution processes to the problematic items contained  $\pm 1$  errors and 6 (5%) contained other kinds of errors. The error analysis indicates strongly that the errors on the problematic items resulted from students' interpretation that the addition or subtraction of the two numbers given in such problems provides the solution.

### Discussion and Conclusion

The major purpose of this study was the examination of prospective secondary mathematics teachers' solution processes when solving problematic addition and

**Table 2.** Percentage of correct solutions for each experimental word problem

| Problem | Number of correct solutions | Percentage of correct solutions |
|---------|-----------------------------|---------------------------------|
| 1       | 14                          | 74%                             |
| 2       | 15                          | 79%                             |
| 3       | 12                          | 63%                             |
| 4       | 6                           | 32%                             |
| 5       | 7                           | 37%                             |
| 6       | 6                           | 32%                             |
| 7       | 8                           | 42%                             |
| 8       | 9                           | 47%                             |
| 9       | 8                           | 42%                             |

**Table 3.** Type of  $\pm 1$  Errors for Each of the Six Problematic Word Problems

| Type of problem | Required operation(s) | Type of $\pm 1$ error | Percentage of students' $\pm 1$ errors |
|-----------------|-----------------------|-----------------------|--|
| II-L            | $(S + D) - 1$         | + 1 error             | 85%                                    |
| II-D            | $(L - S) + 1$         | - 1 error             | 83%                                    |
| II-S            | $(L - D) + 1$         | - 1 error             | 92%                                    |
| III-L           | $(S + D) + 1$         | - 1 error             | 100%                                   |
| III-D           | $(L - S) - 1$         | + 1 error             | 100%                                   |
| III-S           | $(L - D) - 1$         | + 1 error             | 91%                                    |

subtraction word problems involving ordinal numbers to determine the nature of their modeling strategies, interpretations, and errors. A paper-and-pencil test was administered to a total of 19 participants. The test included nine experimental items, three of which were non-problematic and the other six were problematic. The solution of the problematic items is 1 more or 1 less than the addition or subtraction of the two given numbers. Overall, it was found that 90% of the responses contained a formal strategy (addition and subtraction with the two given numbers). The other 10% contained informal strategies (counting techniques and solving a simpler similar problem). It is worth to notice that, although prospective secondary mathematics teachers have more familiarity with anniversaries and their mathematical knowledge is more developed than that of the fifth and sixth graders from Verschaffel, De Corte, and Vierstraete's (1999) study, some of their successful solutions to the problematic items were obtained with counting strategies. This suggests that students knew that the addition or subtraction of the two given numbers does not yield the correct answer to the problem and that some adjustment had to be made but they did not know how to make it. It could also indicate that, at least for the subjects using the counting strategies, their knowledge of addition and subtraction involving ordinal numbers was not completely developed. Both conjectures were verified with interviews conducted with the participants.

While the results for the non-problematic items were less than satisfactory (72% of the solutions were correct), the results for the problematic items were alarming (39% of the solutions were correct), especially given that all but one of the participants were majoring in math. An analysis of errors revealed that 56% of the solution processes to the problematic items used by the students contained  $\pm 1$  errors. That is, it seems that students interpreted that the addition or subtraction of the two given numbers yielded the correct solution to the problematic word problems. Therefore, the model depicted in Figure 2 seems to explain, at least in part, the  $\pm 1$  errors: students failed to correctly interpret the result of adding or subtracting the two given numbers. However, a deeper, perhaps more important question remains: why did some students interpret the result of the addition or subtraction with the two given numbers as the solution to the problematic items? Several hypotheses could be offered to explain

this finding. First, there is the possibility that students approached the problems in a mechanical way because they are used to solve addition and subtraction problems in a straightforward manner. This hypothesis is supported, at least partially, by some students who stated during the interviews that they were not used to think when solving this type of problems because the problems involving addition and subtraction that they have encountered previously had been solved with an addition or subtraction of the two given numbers. A second hypothesis is that some students lack an awareness of informal techniques such as drawing a diagram or solving a simpler similar problem or they may have an underdeveloped repertoire or understanding of such heuristic techniques. I do not offer any direct evidence to support or refute this conjecture. The third hypothesis is that some students do not have a clear understanding of addition and subtraction involving ordinal numbers. This hypothesis is supported by some students who were aware of the problematic nature of the problem but they did not know how to adjust the result produced by the straightforward application of the addition or subtraction of the two given numbers. Some of these students obtained the correct solution by counting techniques. The interviews revealed that these students knew that an addition or subtraction was involved but not how to make the adjustment either on the solution provided by the addition or subtraction of the two given numbers or on the given numbers. It seems then that a plausible explanation for students' lack or interpretation (or misinterpretation) or their use of counting techniques is that they do not have a complete understanding of addition and subtraction involving ordinal numbers. This explanation is in contrast with the one provided by Silver, Shapiro and Deutsch (1993) to understand some middle grade students' solutions to the bus problem when their responses involved 13 or 13 with another number such as a fractional remainder. Silver, Shapiro, and Deutsch reported that about 22% of the students were able to correctly perform an appropriate procedure but did not provide an interpretation for their incorrect numerical answer. These researchers also found that nearly 24% of the students performed the computation procedure incorrectly and provided a numerical solution other than 14 with no interpretation. The researchers argue that both sets of students failed to obtain the correct answer of 14 because they failed to interpret the solution provided by the mathematical procedure. In the case of division problems involving remainders, the lack of interpretation (or misinterpretation) is rooted more deeply on the meaning of the quotient and remainder than on the understanding that the solution of the problem can be represented with a division of the two given numbers. In the present study, in contrast, the lack of interpretation, or misinterpretation, may lie more on an incomplete understanding of the connection between the nature of the enumeration process needed to obtain the solution and the answer provided by the addition and subtraction of the two given numbers. It seems that some of the middle grade students understood that a division with the two given numbers was needed to solve the bus problem but failed to interpret the remainder. In the present study, some

prospective secondary mathematics teachers, in contrast, might not have understood that the addition or subtraction of the two given numbers did not provide the solution to some of the subtraction and addition word problems involving ordinal numbers. It seems then that the semantic feature of Silver, Shapiro, and Deutsch's (1993) model does not completely account for the  $\pm 1$  errors made by the prospective secondary mathematics teachers who chose an appropriate procedure and executed it correctly.

Since a high percentage of errors for the problematic word problems was  $\pm 1$  errors, 91% in fact, it seems that the prospective secondary mathematics teachers need at least some minimal intervention such as telling them that some of such problems are "tricky" or creating a cognitive conflict by asking them to solve simpler similar problems. The cognitive conflict technique was used during the interviews with some of the students who solved all the problematic word problems by adding or subtracting the two given numbers. Some of them immediately realized that some adjustment had to be made to solve the problems correctly.

While the sample size does not allow to generalize any of the results to larger populations of prospective secondary mathematics teachers from the USA or any other country, this study provides useful practical and theoretical information. From a practical point of view, at the very least, this study suggests that some prospective secondary mathematics teachers might approach some problematic word problems, such as the ones examined here, in a mechanical way. This suggests the introduction of problematic word problems in the school curriculum so that future teachers learn to approach word problems with a realistic perspective. Another contribution of this study is that some prospective secondary mathematics teachers might have an incomplete understanding of subtraction and addition involving ordinal numbers and these teachers will need more than a minimal intervention. Another contribution of this study is related to helping prospective secondary mathematics teachers develop a disposition to provide their students with problematic word problems so they (their students) learn to solve such problems realistically, and, as it is the case with the problems used in this study, develop a deeper understanding of addition and subtraction involving ordinal numbers. From a theoretical point of view, the findings help us to better understand some of the psychological aspects of learning mathematics within the context of problematic word problems. The results also shed some light on some aspects of Silver, Shapiro, and Deutsch's (1993) referential-and-semantic processing model as discussed above.

# A FRAMEWORK FOR POSING TECHNOLOGY-RICH MATHEMATICS PROBLEMS

Nicholas Oppong  
University of Georgia  
noppong@uga.edu

This study investigated how secondary school preservice teachers used the *Critique; Compare; Compose; Pose and Check* (C<sup>3</sup>PC) strategy to engage in posing, sharing, and critiquing technology-rich mathematics problems. The study attempted to investigate the psychological aspects of teaching and learning mathematics in a technology-enhanced classroom. C<sup>3</sup>PC helped students to think more deeply about mathematics, facilitated generalization, and empowered students to solve difficult problems. It encouraged reflection on promising practices; solving problems; and reconstructing knowledge of the process of growth and learning. The implications of this study serve to promote reflection by increasing preservice teachers' awareness of their own values of mathematical problems, and perspectives about the teaching and learning of mathematics, and by encouraging them to entertain perspectives different from their own.

## Theoretical Framework

Many educators and education groups have called for fostering problem posing in mathematics students (Freudenthal, 1973; National Council of Teachers of Mathematics, 2000; Polya, 1954). Problem posing has been identified as of central importance in the discipline of mathematics and in the nature of mathematical thinking (Silver, Marmona-Downs, Leung, & Kenney, 1996).

The availability of technology and the innovative ways that it can be used provides an opportunity and a challenge to mathematics teachers (Kaput, 1988). According to Clarke (1999), computers used as powerful educational tools are providing the possibility of amplifying human ability, by enabling users to undertake tasks previously considered too difficult, too tedious, or too time-consuming and by providing a tool for the development of cognitive skills. However, not all types of mathematical problems call for the use of technology for effective solutions. On the contrary, most textbook problems can be solved equally as well with paper and pencil as with technology. The use of technology to enhance problem posing, combined with technology-assisted explorations and solutions of the problems, may be a powerful pedagogical alliance that may lead students to think more critically.

According to Moses, Bjork and Goldenberg (1990), the teacher is the essential ingredient in the problem posing process. They propose four main ideas to foster problem posing: (1) use problems in textbooks as a basis for problem posing, (2) avoid questions that have unique answers, (3) create a classroom climate where teachers model the problem posing process for their students, and (4) use technology to promote problem posing. In addition, English, Cudmore, and Tilley (1998) suggest that problem posing paired with problem critiquing provides an effective vehicle for fostering analytical skills in the mathematics classroom.

I propose a modification of Moses, Bjork and Goldenberg's (1990) framework that includes a five-phase model to foster the posing and checking of technology rich problems: Critique; Compare; Compose; Pose and Check (C<sup>3</sup>PC). Technology-rich problems are mathematics problems that could be solved effectively using technology. The first phase in the C<sup>3</sup>PC process is to *critique* school mathematics textbook problems, problems published online at the various mathematics sites, and problems written by the teacher and students. The second phase, *compare*, involves contrasting and classifying the problems examined into those that could be solved easily with paper and pencil and those where the solution can be enhanced using technology. The third phase, *compose* provides students with simpler problems or situations to create more complex problems. They may also be expected to decompose complex problems into simpler ones. The fourth phase requires students to pose original problems. The last and fifth phase, *check*, requires students to reexamine the problems they posed. The check process is endless with each new problem posed, critiqued, compared, and composed.

### Method and Data Sources

This exploratory investigation was conducted to describe the nature of problems posed by preservice teachers that call for the use of technology for effective solutions. The research questions were:

1. What factors motivate students to write technology-rich mathematics problems?
2. How helpful was the C<sup>3</sup>PC strategy for posing technology-rich problems?
3. What do technology-rich problems posed by students say about their understanding of a mathematics concept?

The participants were 23 secondary school preservice teachers in their junior year enrolled in a *Technology and Secondary School Mathematics* course. This course included the use of various technology tools to investigate mathematical topics at the secondary level. Participants were given class time to examine and discuss mathematics problems. Each problem asks the students to employ the C<sup>3</sup>PC strategy to determine its technological merit. The instructor also modeled the formulation of technology-rich problems in class. An example is given below:

You have the following students in your class: Frank, Elizabeth, Ophelia, and Felix. Frank made 98, 85, 81, and 85 on four tests all out of 100 points. Elizabeth made 88, 85, 98, and 87. Ophelia made 83, 83, 83, and 87. Felix made 73, 92, 100, and 87. The first two tests account for 20% each, and the last two tests account for 25% each of the final grade. The only other grade you have is for their notebooks. Your school sets the lowest passing grade of C at an average of 70 up to 79, B at 80-89, and A at 90 and over.

- (a) Which of the students could receive an “A” grade? A “C” grade? Why?
- (b) Is it possible for any of your students to fail? Explain.
- (c) If Frank scored 75 on his notebook, and Ophelia scored 95, overall, which of the two students is the better student?
- (d) Could Elizabeth be the best student? If not why? If yes, what minimum notebook grade should she receive to be the best student?

Even though this problem could be solved using paper and pencil, the solution could be better illustrated using spreadsheets.

Data sources for the study included: student generated problems, follow-up class and E-mail discussions, individual interviews, and a town meeting. Participants were expected to pose two problems each week. The best problem of the 46 problems posed each week was posted on the Web. Selected student-generated problems were also used on tests. It was expected that at least 50% of students' problems be the type that called for the use of technology for effective solution. This method generated over 230 technology-rich problems from the participants. A “problem of the week file” and follow up discussions, observations of students writing mathematical problems on the spot, and interviews of selected students were the main sources of data. Using “talk aloud” protocol, participants' problem posing processes were documented. E-mail and class discussions of the problems were ongoing throughout the semester. Other sources of data were through whole class “town meeting at the end of the semester.” At the “town meetings” the results, as they were emerging from observations and interviews, were shared with the participants for their feedback.

The constant comparative method of Glaser and Strauss (1967) was used to understand the nature of problems posed by the preservice teachers. Efforts were made to uncover evidence of patterns, similarities, and differences in the problems posed by the participants. Participant observation and open-ended interviews were used to answer the research questions.

### **Results**

Most preservice teachers valued the C<sup>3</sup>PC process and thought it helped them to have a deeper understanding of the concept they were studying and was also relevant to their future teaching careers. Although most students could pose technology rich problems, their mathematical understanding varied. A synthesis of some of the results are: (1) Preservice teachers were motivated to pose technology rich problems by external rewards such as a chance to have their problems posted on the web or used on a test. (2) They viewed the C<sup>3</sup>PC process as relevant to their future teaching careers. Students who were successful problem posers were more likely to succeed in the course and in the program. (3) The problems students posed provided a medium for analyzing their understanding.

What do the problems students pose say about their understanding of a concept? Three students were unable to pose technology-rich problems. Students with a strong foundation were able to explain and extend their problems in class discussions, however, those with limited mathematics understanding were unable to.

# IDENTIFICATION OF STRATEGIES USED BY FIFTH GRADERS TO SOLVE MATHEMATICS WORD PROBLEMS

Julio César Arteaga Palomares  
CINVESTAV-IPN, México, DF, México  
jarteaga@mail.cinvestav.mx

José Guzmán Hernández  
CINVESTAV-IPN, México, DF, México  
jguzman@mail.cinvestav.mx

When students confront arithmetic or algebraic word problems, they develop ideas and notations during the processes of solving them by using various arithmetic strategies. Those ideas and notations are the basis for solving that type of problems. Is it possible to aid the development of students' algebraic thinking during their transition from arithmetic to algebra? We think that a way of doing so is by presenting them with different types of problems—as proposed by Bednarz and Janvier (1996)—and encouraging their reasoning and development of strategies linked to their arithmetic thinking. Hence, the identification of strategies used by fifth graders when solving algebraic word problems is of outstanding importance for finding effective ways to aid students during their transition from the arithmetic to the algebraic thinking. Results obtained in this research study show that with these types of mathematics word problems, students generate strategies that at certain moment become useful for their transition to the algebraic thinking.

## Background

In the plan and programs for elementary school education (grades 1-6) in México, a methodological approach based on problem solving is proposed for the teaching of mathematics. Recommendations in these official documents emphasize dialogue, interaction, and confrontation of viewpoints as important activities for promoting learning and the construction of knowledge. It is argued that by implementing these activities students will view mathematics as a functional and flexible tool for solving problems posed to them (SEP, 1993, pp. 49-70).

However, elementary school teachers seldom put these recommendations into practice and, in the school environment, students perceive mathematics as complex and governed by rules under which their learning depends mainly on memorization. Students in the lower secondary level of education (grades 7-9) have a similar perspective about mathematics. When students in this level (ages 12 to 14) solve algebraic problems, for instance, they usually have recourse to rules and procedures with no reflection on these; they believe that this type of activities represents the essence of algebra. Kieran (1988) reported that students in the lower secondary level of education are often unable to apply their knowledge of basic algebra when solving problems.

Solving algebraic word problems enhances students' attitudes for searching and producing conjectures that in a middle term will allow them to acquire algebraic notions such as equation, unknown, generalized number, variable, and function.

Therefore, by means of solving this type of problems, it is possible to help students make the transition from arithmetic to algebra.

The passage of students from the elementary to the lower secondary level of education underlies the development of new mathematical abilities. Several authors have reported that students encounter great difficulties during their transition from arithmetic to algebra—Filloy and Rojano (1989), Herscovics and Linchevski (1991), Kieran (1981, 1988), Kieran and Chaloug (1993), Booth (1984), and Bednarz and Janvier (1996), among others.

In the trend of research that approaches the area of transition from arithmetic to algebra, Filloy and Rojano (1989) introduced the concept of *didactic cut* to characterize the transition in the specific realm of solving equations. Herscovics and Linchevski (1991), in a similar trend of research, described that a *cognitive shift* occurs when students operate on the unknown. Bednarz and Janvier (1996) made a different contribution to this area of educational research: they investigated the conditions that allow students to construct algebraic arguments in a context of solving mathematics word problems.

In a previous research paper, Bednarz and Janvier (1994) presented an analysis of arguments produced by students when solving either arithmetic or algebraic problems. These researchers discovered that before introducing students to algebra, they put different stable profiles of arithmetical reasoning into play when confronted with different types of problems traditionally presented in algebra.

One objective in the investigation by Bednarz and Janvier (1996) was to clarify the conditions under which, in a context of solving word problems, students' algebraic thinking emerges and develops. They also studied two basic aspects for the characterization of such problems: nature of the problems—their structure—and the relative difficulty for students to solve them. Moreover, they noticed the importance of identifying the general structure of a problem according to the involved (known and unknown) quantities, the relationship between them (connection between quantities), and the type of relations implied (additive or multiplicative comparison).

Thus, according to the structure of problems, Bednarz and Janvier (1996, p. 123) classified them as arithmetic or *connected*, and algebraic or *disconnected*. With connected problems, it is possible to build bridges between known information and students can work from the known to the unknown. Disconnected problems allow no direct relation between known and unknown information to be established.

Hence, these authors could show the complexity of algebraic word problems usually posed to students during their regular courses of lower secondary education. They also emphasized that the knowledge of strategies applicable in the solution of arithmetic problems is the basis for the transition from arithmetic to algebra. In the selection of the word problems for our research, the characterization proposed by Bednarz and Janvier (1996) was of fundamental importance.

### The Research Study

The purpose of our investigation was to identify arithmetic strategies that fifth graders have recourse to and the way they use them for solving mathematics word problems—above all, those problems related to algebra. The research activities for this study initiated with 35 fifth graders (ages 11 and 12) of a public school in an urban area. Students in this group had an acceptable performance in mathematics, although they had little experience in problem solving.

Since working with 35 students would make it difficult to observe their interactions and their processes for solving problems, only 15 students were selected for the experimental phase: five high-achieving students, five average achievers, and five low-achieving students. We based our selection on the analyses of results obtained from a diagnostic questionnaire (DQ) applied to all students in this group. Then the selected students formed working teams, each with one student of each level of achievement.

The difficulties students had when trying to solve the selected problems we presented them were evident. Thus, we reconsidered the question posed by Bednarz and Janvier (1996): *Is it possible to help students make the transition from arithmetic to algebra?* We think that it is possible to aid the development of students' algebraic thinking during their transition from arithmetic to algebra. A way of doing so is by presenting students with problems of different nature—as proposed by Bednarz and Janvier (1996)—and encouraging their reasoning and development of strategies linked to their arithmetic thinking.

### Methodology

During the first phase of the investigation, we looked for and designed problems to elaborate the DQ. As a part of the search, we revised mathematics textbooks of the last cycle of elementary education (grades 5-6) and of the first grade of lower secondary education (grade 7). The questionnaire students had to answer contained arithmetic word problems mainly. In the analyses of the responses by students, we noticed some arithmetic difficulties they had and we could identify some of their problem solving abilities as well—which were deficient.

Based on the identification of students' previous arithmetic knowledge, we designed 22 working sheets with an algebraic problem each (for examples of these problems, see Appendix) and planned the manner in which we should pose algebraic problems. The purposes for the elaboration of those working sheets were to:

- present students with problems traditionally studied in school algebra;
- observe the advantages of working in teams;
- identify arithmetic strategies students use; and
- enhance students' development of abilities to solve algebraic problems.

In the second phase of the investigation, during three weeks we had 15 working

sessions of about 50 minutes each. All sessions were video-recorded and, additionally, the researcher took notes about features of each.

Students approached every proposed problem by working in a collaborative environment; that is, they worked in teams during this experimentation phase. Due to this way of working, it was easier to identify the strategies students used when solving word problems.

At the beginning of each working session, the researcher would ask students to read the statement of the problem carefully so that they could understand what was required. We discussed with them what it means (a) to understand the problem, (b) the selection and development of a strategy, and (c) the verification of a solution. Moreover, we suggested them to use a pen to do all their writing during the process of solving a problem.

Students would re-read the problem and decide the way to approach it by working in teams. The three students in each team discussed and tried strategies, checked their results, and registered their trials in the working sheets. An example of those discussions is the solution process in one of the teams for the following problem.

The perimeter of a rectangular plot of land is 102 meters. The depth of the plot is double its width. What is its depth? What is its width? (Adapted from: Alarcón, Bonilla, Nava, Rojano, & Quintero, 1994, p. 162)

Researcher [R]: How did you solve the problem?

Student 1 [S1]: First, we divided 102 by 2 [student writes the division] and we got 51.

R: What did you do with that number?

Student 3 [S3]: Then, we divided 51 by 2 [student writes the division] and we got 25.5. This was not right because when multiplying 25.5 by 51 [student writes the multiplication] we got 1300.5 ... So it was wrong.

S3: Next, we decided to divide 102 by 3 [student writes the division] and we got 34.

R: Was this result useful?

Student 2 [S2]: We wrote 34 plus 34 [student writes the addition] and we got 68, but we did not have the width yet.

S2: We thought of 34 divided by 2 and we got 17.

R: How do you know that the solution you found is correct?

S1: Because we multiplied 17 by 2 [student writes the multiplication] and we got 34.

S1: Then, we added 68 plus 34, and we finally got 102.

When necessary, the researcher participated by asking questions and giving suggestions to students with the purpose of encouraging them in their work processes of solving the problems. Moreover, the researcher aided students to overcome difficulties that appeared at any point during the solution processes. This help provided to students consisted of asking questions to promote their reasoning and lead them to analyze the problem from a different perspective to the one they had adopted. The following are some of the questions asked.

Regarding the way of posing the problem:

Have you understood the problem?

Can you explain it to your teammates?

Can you explain what the problem is about with your own words?

What do you want to find?

Do you have any difficulty in understanding any part of the problem?

What part of the problem you do not understand?

What do you know?

What you do not know?

What are the data of the problem?

Did you identify the relevant information?

Does the problem have any information that is not relevant?

Can you make a sketch or draw a picture to interpret or illustrate the problem?

Regarding the solution process:

Do you have any idea on how to solve the problem?

Have you ever solve any similar problem?

How are you going to solve it?

What strategies could be useful to solve the problem?

What are the conditions of the problem?

What are you doing now?

Are you getting somewhere with that?

How does that relate with the solution?

Could a table or a graphic be useful?

Can you think of another way or method to solve the problem?

After solving the problem:

How do you know that the solution you found is correct?

What do you do with that result?

Does your answer make sense with respect to the conditions of the problem?

What strategies did you use?

Can you check or verify your solution?

Could you have solved the problem in a different way?

How would you do that?

Can you express with words what you have checked?

What do you think about the solution methods used by your classmates?

Thus, the role played by the researcher during this phase was that of facilitator and guide. After students had finished solving a problem, we did a group revision of the solutions found. This comparison was helpful for analyzing the solution processes and strategies used. Our intention was to leave no doubts as to the solution and verification of results. We must emphasize that this group revision allowed students to identify the strategies that emerged. Then, for solving similar problems they could have recourse to those strategies they thought were more useful.

During the working sessions, a collaborative and trusting environment was created. Students could freely exchange their ideas and they rotated the responsibilities of coordinating and presenting the teamwork. At the beginning of the experimental phase, high-achieving students took the initiative for coordinating the teamwork. As the working sessions progressed, average- and low-achieving students had a relevant participation both in the teamwork and in the group revisions of the work done.

During the third phase of the investigation, students had to answer a final questionnaire (FQ) individually. (We had previously designed the FQ with problems similar to those in the DQ.) Problems in the FQ aimed at: (i) exploring the individual progress of students during the experimental phase, and (ii) identifying strategies used by students for solving algebraic problems.

### **Discussion of Results**

By working in teams, students could discuss different ways of interpreting the same problem and come to an agreement as to the most convenient way of approaching it. Besides, due to the group revisions and the use of the different solution strategies that emerged, they constructed new knowledge. At the end of the experimental phase, we observed that students could efficiently use the strategies analyzed during the group revisions. At the beginning, non-systematized trial and error was the strategy they used the most.

Moreover, the lack of reflection by students on the initial conditions of the problems when preferring the use of the basic arithmetic operations (addition, subtraction, multiplication, and division) was remarkable. Additionally, students systematically

valued the results of their own activities as well as the solution criteria of their teammates. Confronting their solution processes was also an achievement.

The strategies systematically used by students during the experimental phase were the following:

- S1*. Propose a number and check it to find a solution.
- S2*. Divide one of the quantities into parts "to be distributed," followed by the search of numbers ending in 0 or 5, and, then, approximate to the desired quantity adding one by one.
- S3*. Base their work on the design of a drawing to find the solution.
- S4*. Construct a table for comparing the data and approximate the solution.
- S5*. Draw a number line to compare paths covered by a series of *jumps*.
- S6*. Mechanical use of basic arithmetic operations (addition, subtraction, multiplication, and division), that is, without any reflection on the initial conditions of the problem.
- S7*. Use of the rule of 3.
- S8*. Preference for the use of mental arithmetic without having to write the operations used (numeric answer).

At the beginning of the experimentation, the strategy most frequently used by students was *S1*. However, they soon realized the disadvantages of having to do several operations to find the solution. Hence, thereafter they preferred to change to the use of strategy *S2*. Few students used *S1* for answering the FQ (8.6%).

When using strategy *S2*, students first approximated the desired quantity by dividing; then, they approximated it with quantities ending in 0 or 5, and, finally, they tried with adding one by one to a number until they found the solution. Students preferred this strategy both in the experimental phase and in the FQ (49.3% used it in the FQ).

The solution of the following problem illustrates what has been just described above (see Figure 1).

Seventy-eight (78) candies are distributed among Edgar, Juan, and Saúl. Juan receives 3 times as many candies as Edgar, and Saúl receives two candies less than Edgar. How many candies does each boy receive?  
(Adapted from: Alarcón et al., 1994, p. 166)

Some students found strategy *S3* very useful during the experimental phase, especially for grasping the problem posed. Nevertheless, students seldom had recourse to strategy *S3* in the FQ (0.6%). Only 4.6% of students had recourse to a table (*S4*) to solve some problems. To compare traveled distances in problems of "reaching," 8.6% of students based their work on a number line, strategy *S5*, a percentage similar to the one for *S1* and *S8*.

Figure 1

Strategy S6 was used 15.3%. Generally, students did arithmetic operations with the data of the problem without any reflection on the conditions given at the beginning of it. It is evident that, in a school environment, students usually proceed so. School instruction promotes strategy S7 to solve certain kind of problems. When the experimentation started, S7 was preferred; however, students participating in this research study soon realized that S7 was not useful to solve the proposed problems and its utilization was reduced (2.0% in the FQ).

The strategy of mental arithmetic, S8, was also important for students: once they had understood the conditions of the problem, they did operations without having to write them down. Although it is common for students to use this strategy in their daily work, generally teachers do not accept it and demand from students to write down the operations they carry out mentally. From the analyses of results of the FQ, besides observing that students had recourse to the arithmetic strategies that emerged during the experimental phase, we can claim that they did develop abilities to solve problems of different nature.

### Conclusions

It is complicated for students to transit from arithmetic to algebra. The difficulties they have when solving arithmetical and algebraic word problems is a clear evidence of this. This evidence is more apparent when we realize that the strategies and reasoning of students for solving algebraic problems are fundamental for the construction of their algebraic thinking.

We think that it is possible to aid students' development of algebraic thinking during the phase of their transition from arithmetic to algebra. We think that a way of doing so is by presenting them with different types of problems—as proposed by Bednarz and Janvier (1996)—and encouraging their reasoning and development of strategies linked to their arithmetic thinking.

At the beginning of the experimental phase, we observed that students lacked concentration when they tried to solve algebraic problems. They even claimed that there was not enough information and that therefore they could not approach the proposed problems. Then, when students attempted to solve one of the problems posed to them, they tried different ways. Their main strategy was *S1*, but they soon realized that it was not necessary to do so many computations. Thus, as a first approximation, they started systematizing their strategies using quantities ending in 0 (by the easiness to operate with them, as can be seen in Figure 1).

Later, they continued with *controlled quantities*, that is, they had recourse to strategy *S2*. Eventually, this strategy became the most used. For instance, some students perceived the structure of the problem in an arithmetic context, and then they solved it by means of strategy *S2*.

Despite that in some occasions students did not take into account some portion of the information contained in the proposed problem, there was a positive evolution of most students to solve the problems as the experimental phase progressed. Moreover, students would check their answer to the problem according to the initial conditions of it. This was not easy, for students were used only to find a result without having to verify it. Thus, verification of the answer by students was an important accomplishment.

Now, with respect to the purpose of the investigation, the identification of strategies that fifth graders have recourse to for solving mathematics word problems, we can claim that students used informal arithmetic strategies—non-school strategies—to solve them. These strategies can evolve whenever students are stimulated to work with those relations and transformations immersed in the text of the problem. By means of an adequate intervention of the instructor, emphasizing correctly the arithmetic experience of the students, it is possible to make them come close to the algebraic thinking by designing ad hoc activities and problems.

By taking into account the complexity of word problems according to the characteristics proposed by Bednarz and Janvier (1996), we can select problems and rank them suitably for the design of a didactical intervention. Such a didactical intervention would support—in a controlled manner—the evolution of student' arithmetic reasoning toward their algebraic reasoning.

## **Appendix**

### **Examples of Problems Included in the Working Sheets**

1. We want to distribute 100 chocolates among Saúl, Ricardo, and Nelson in such a way that Ricardo receives 4 times as many chocolates as Saúl, and Nelson receives 10 chocolates more than Ricardo. How many chocolates does each boy receive? (Adapted from: Alarcón et al., 1994, p. 165)
2. We want to distribute 91 bracelets among Rita, Luisa, and Candy in such a way that Rita receives 3 times as many bracelets as Luisa, and Luisa receives 3 times as many as Candy. How many bracelets does each girl receive? (Adapted from: Alarcón et al., 1994, p. 165)
3. An airplane flew 12 kilometers in 72 seconds. What was its average speed? How long will it take the airplane to fly a distance of 1800 kilometers? (Adapted from: Cárdenas et al., 1976, p. 199)
4. An automobile leaves from México City to Nayarit at an average speed of 40 kilometers per hour. Two hours later another automobile also leaves México City with the same destination at an average speed of 60 kilometers per hour. How long will it take the second automobile to reach the first one? (Adapted from: Preciado & Toral, 1971, p. 173)
5. There are three piles of flat bottle caps. The first pile has 5 bottle caps less than the third, and the second pile has 15 more than the third. The total number of flat bottle caps is 31. How many bottle caps are there in each pile? (Adapted from: Alarcón et al., 1994, p. 166)
6. The perimeter of a rectangular plot of land is 102 meters. The depth of the plot is double its width. What is its depth? What is its width? (Adapted from: Alarcón et al., 1994, p. 162)

# **PROBABILISTIC MISCONCEPTIONS: A 50/50 APPROACH AMONG MIDDLE AND HIGH SCHOOL STUDENTS**

Laurie Rubel

University of Wisconsin - Madison

lhrubel@aol.com

This paper reports selected findings from a larger study on student probabilistic reasoning abilities. Students in grades 5,7,9 and 11 at a private school for boys in New York City ( $n = 173$ ) completed a Probability Inventory, which required students to answer and justify their responses to ten items. Supplemental clinical interviews were conducted with 33 of the students to provide further detail about their reasoning on these items. A 50/50 approach was typical, especially among younger students, by which they over-generalized the probability of a single trial of a coin to a compound situation. A student using the 50/50 approach would indicate “correctly” that the probability of two coins resulting in one heads and one tails is 50% but also that the probability of any number of coins resulting in any outcome is 50%. The 50/50 approach was also used by students when comparing the likelihood of 7 tails on 10 tosses with 700 tails on 1000 tosses. 40% of the sample used a 50/50 approach on at least two items of the Probability Inventory.

## **Purpose of the Study**

In articulating standards for school mathematics, the National Council of Teachers of Mathematics (NCTM) indicates that students, by graduation from high school, should be able to “develop and evaluate inferences and predictions that are based on data” (NCTM, 2000). The NCTM specifies, “Middle grades students should learn and use appropriate terminology and should be able to compute probabilities for simple and compound events...and high school students should compute probabilities of compound events and understand conditional and independent events.” (NCTM, 2000) The inclusion of probability and data analysis as one of the ten NCTM standards reflects an increasing emphasis on data and the importance of the ability to infer conclusions based on data. This type of decision-making is commonplace in the course of everyday life, as well as in professional fields as diverse as psychology, political science, physical sciences, economics, engineering and medicine.

The main objectives of the larger study were to explore the following probabilistic misconceptions among people of various ages: representativeness, effect of sample size, availability, the conjunction fallacy, and assumed equiprobability in a special class of conditional probability problems. Previous studies of such misconceptions have focused on the decision-making abilities of adults, typically using college students as subjects. The focus of this study was to broaden our understanding of probabilistic misconceptions among middle school and high school students, including an analysis of the effects of age. The current report presents one theme found among the sections of the larger study dealing with coin problems.

### **Brief Theoretical Framework**

Examples of research identifying probabilistic misconceptions from a cognitive psychological point of view abound (Konold, 1993; Nisbett & Ross, 1980; Tversky & Kahneman, 1971, 1973, 1982, 1983). In recent years, as probability and statistics receive greater attention in school curricula, mathematics education researchers have made efforts to identify misconceptions in this area, seeking also to explore how teachers and school programs can intervene and change these misconceptions. (Fischbein 1975, 1991; Fischbein & Schnarch, 1997; Konold, 1989; Konold, Pollatske, Well, Lohmeier, & Lisbon, 1993; Shaughnessy, 1981). While not directly dealing with probability, other research in mathematics education focuses on students' misconceptions, intuitions, and inconsistencies in a variety of mathematical contexts, and the role they play in teaching and learning (Fischbein 1987; Tirosh & Graeber, 1990; Tirosh and Stavy, 2000; Vinner, 1990).

Fischbein and Schnarch (1997) conducted a preliminary study to determine the evolution of probabilistic misconceptions with respect to age. Their study examined samples of twenty Israeli students in each of grades 5, 7, 9, and 11, along with eighteen college students. Interestingly, their results indicate that certain probabilistic misconceptions increase with age, others decrease with age, and others are relatively stable. The current study implemented some of the questions used by Fischbein and Schnarch (1997), supplemented by additional questions relating to probabilistic misconceptions as well as traditional probability questions. The current study both replicates and extends Fischbein's work by studying samples twice as large, approximately forty students in grades 5, 7, 9, and 11 and deepens the potential to understand student responses by including student justifications and clinical interviews as part of the methodology.

### **Methods**

The two data gathering phases of the study were conducted at a private school for boys, known for its academic excellence, in New York City. All students in grades 5, 7, 9, and 11 were selected as potential participants, resulting in a total of 173 subjects. These students worked independently on a written Probability Inventory for the duration of a class period (40 minutes). The second phase of data gathering was the clinical interviewing of thirty-three students, representing each of the age groups. The researcher conducted all of the interviews, using a standstill video camera for recording. The primary goal of each interview was to gain greater detail by using "How did you get this?" or "Why does this work?" types of questions. Borovcnik and Peard (1996) describe a process called "interview teaching," in which students are confronted with items and then given an opportunity to individually explain answers to those items. The teacher can then use these responses to "provoke insight" by "maneuvering the learners into a situation where this approach would become obviously absurd." The researcher used the "interview teaching" approach with regard to misconceptions that surfaced in the course of the clinical interviews.

## Selected Results

### Two Coin Item

The Two Coin Item asked students to determine the likelihood that Eminem gets one heads and one tails on a toss of two fair coins. Nearly all students in grades 5 and higher were successful in computing the probability of a simple event. Students in grades 5 and higher had difficulties, however, with determining the probability of a compound of two events. In responding to the Two Coin item, only 55% of the students, stable across all ages, responded  $\frac{1}{2}$ . Some students justified this correct answer either by listing the complete, equiprobable sample space or by using conditional reasoning. However, most of the younger students who gave the correct answer, and 36% of the entire sample, used a “50/50 approach,” by which they over-generalized the probability of a single event to the compound situation. The 50/50 approach perhaps explains the discrepancy reported by Carpenter, Corbitt, Kepner, Lindquist, and Reys (1981) regarding student performance on items related to compound events on the second National Assessment of Educational Progress. While more than two-thirds of seventeen year olds were able to compute the probability of one head and one tail on two fair coins as  $\frac{1}{2}$ , 58% of 13 year olds and 50% of 17 year olds also indicated  $\frac{1}{2}$  as the probability of getting *two* heads on two coins.

Based on their written justifications of their answers as well as comments made in the interviews, we can see that many of the younger students arrived at the correct answer to the question by using reasoning that would also cause them to indicate that there is a 50% chance for *any* of the possible outcomes on two coins, similar to the results of Fischbein, Nello, and Marino. (1991), Lecoutre (1992), and Fischbein and Schnarch (1997). We label this the “50/50 approach” in that students over-generalize the 50/50 nature of an individual flip of a single coin to compound events. This is an extension of the equiprobability bias described by Lecoutre (1992), used to denote the intuition that a tail and a head would be as likely as two tails on two coins.

An example of the 50/50 approach and its connection to the equiprobability bias is found in the following excerpt from an interview with Max, a 9<sup>th</sup> grader.

Researcher: “Eminem tosses two fair quarters in the air. What are the chances that they land so that there is one heads and one tails?”

Max: “50% because every time there’s a 50% chance.”

Researcher: “What if I changed the question and asked you to find the probability that he gets two heads?”

Max: “50% because there’s two sides. Again, you can never predict.”

We see that Max believes both probabilities are equal, according to the equiprobability bias, and, also, that both probabilities are 50%, according to the 50/50 approach.

At this point, the researcher attempted to direct Max to think about the sample space of this experiment by using actual coins.

Researcher: "What could happen when you toss two coins?" (There are two coins on the table)

*Max shows the cases HT, TT, and HH with the actual coins.*

Researcher: "What's the probability of getting two heads?"

Max: "I think 50% because this coin has 50% of being a heads and this coin has 50% of being a head."

Even though he showed a sample space of size three, Max continued to use the 50/50 approach. At this point, the researcher attempted to create a conflict by having Max indicate the probabilities of two heads, two tails, and one of each, and then find the sum of those probabilities. Using the 50/50 approach, one would have the sum of the probabilities exceeding 100%, which could potentially create a conflict for the learner.

Researcher: "How about two tails?"

Max: "50% because it's like the heads again."

Researcher: "How about heads and tails, like this or like this?" (I show him with the coins)

Max: "50%."

Researcher: "So how many 50% chances do we have, can you add them up?"

Max: ".....2.5."

Researcher: "Is it ok to have probabilities add up to 2.5?"

Max: "A 2.5 probability? I mean, I guess it must be."

Another example of the 50/50 approach is demonstrated in the following excerpt from an interview with Daryl, a 7<sup>th</sup> grader. In this interview, the student responded using the 50/50 approach. The researcher attempted to create a cognitive conflict by adjusting the number of coins.

Daryl: "It's a 50% chance each so he has an even chance of getting both. Even if you have two quarters, there's still going to be a 50% chance."

Researcher: "What if we had 3 quarters? What's the probability that we get all tails?"

Daryl: "I still say 50%."

Researcher: "Why's that?"

- Daryl: "Because unless something affects the way the quarters come down, it's still going to be equal."
- Researcher: "What if we had 100 quarters? What's the probability that we get all tails?"
- Daryl: "Half-way."
- Researcher: "So if we threw up 100 quarters, you think we'd have a 50% chance that every single one of them lands on tails?"
- Daryl: "Yeah."
- Researcher: "Ok – what about 100,000 quarters?"
- Daryl: "That's a lot. But it's still 50%."

This student believes that any outcome of any number of coins is 50%, a mammoth over-generalization of the single coin model.

Other common responses to the Two Coin item were  $1/3$  and  $1/4$ . In an era where increasingly great emphasis is placed on standardized testing results, these findings point to two serious difficulties. First, as we see in the results of the Two Coin item, it is possible for students to answer a question correctly, for reasons that are incorrect. Standardized test items must, therefore, be carefully studied prior to their use. Second, the results of this study show that it is possible for a wrong answer to be more mathematically sophisticated than a right answer. A student who determined a non-equiprobable sample space for the Two Coin item to arrive at an answer of  $1/3$  arguably knows "more" than a student who gives the correct answer using the 50/50 approach.

### **Four Heads Item**

The Four Heads Item asked students to determine the most (and least likely) outcomes of the fifth toss of a fair coin that has just resulted in four consecutive heads. Most of the 7<sup>th</sup>, 9<sup>th</sup>, and 11<sup>th</sup> graders (89%, 70%, 83%) said that there is no most likely outcome on the fifth toss of a fair coin which has produced a streak of four consecutive heads. The correct response rate slightly *decreased* across students from grade 7 to grade 11, perhaps as a result of the stronger presence of the 50/50 approach among younger students. While 17% of all students did commit the gambler's fallacy by saying that a tails would be most likely after a string of four heads, 9%, or 15 students, said that another heads would be the most likely outcome since that follows "the pattern."

### **Coin Sequences Item**

The Coin Sequences item asked students to choose a most (and least) likely, if any, sequence of coin tosses among HTHTHT, HHTHTT, HHHTTT, and TTTHTT. About two-thirds of the students indicated that each of the coin sequences listed in the

Coin Sequences item is equally likely. However, only 59% of those students justified this answer referring to independence of trials or the significance of order. Students in grades 5 and grade 7 used the 50/50 or outcome approaches more often than referring to independence or order, while most of the older students, in grades 9 and 11, who answered the question correctly also justified their answer correctly.

Examining the sequences HTHTHT, HHTHTT, HHHTTT, and TTTHTT, the sequence HHTHTT is the most representative, according to Tversky and Kahneman's definition of representativeness, in that it has both three heads and three tails as well as a seemingly random ordering. However, only ten students, or 6% of the sample, chose HHTHTT as the most likely sequence. On the other hand, 13%, or 22 students, said that HTHTHT was the most likely. Another 18 students, or 10%, indicated that any of the sequences with three heads and three tails would be the most likely. This means that nearly a quarter of the sample did not relate to the random process of each individual coin flip but only to the overall composition of the number of heads and tails in each sequence.

### Effect of Sample Size

Two questions were asked to determine student perception of the effects of sample size. The first question had a familiar real-world context and the second related to a coin situation. All students were asked the Yankees item prior to the Coins Sample Size item. The Coins Sample Size item asked students to compare the likelihood of a result of 7 tails on 10 tosses of a fair coin with a result of 700 tails on 1000 tosses of a fair coin, with an option that they are equally likely. 72% (124 students) of all students indicated that 7 tails out of 10 tosses is as likely as 700 tails out of 1000 tosses. Most students who indicated that the events are equally likely on both items gave justifications for their choice based on equal ratios, equal fractions, or equal percentages. This is another instance of the intuitive rule, Same A Same B, described by Tirosh and Stavy (2000). While in most cases, students justified this answer by writing that 7/10 is equivalent to 700/1000, some students blended their conception of the 50/50 approach with the effect of sample size and knowledge of ratios.

Students using the 50/50 approach believe that *any* two outcomes involving coins are equally likely. In other words, for instance, in response to the Coins Sample Size item, 9<sup>th</sup> grader Niles said:

Niles: "They're equally likely because there's still a 50/50 chance."

Researcher: "What about the likelihood of getting 10 tails out of 10?"

Niles: "That's equally likely."

Niles does not seem to relating to the equal proportions whatsoever; instead, his decision is based on a misconception of the meaning of 50/50.

### Consistency of 50/50 Approach

There were four items on the Probability Inventory that dealt with trials of coin flipping: the Two Coin item, the Four Heads item, the Coin Sequences item, and the Coins Sample Size item. We have described the incidence of an approach called the “50/50 approach” by which students over-generalize the probability of a single trial to compound events. How consistent is this approach? To answer this question, we can examine profiles of students on those four items. On the Four Heads item, the 50/50 approach is effective: a student reasoning with the 50/50 approach will write the correct answer (50%) and will justify this on the basis of the probability of a single trial of one coin. However, a student using the 50/50 approach on the Coin Sequences item will again write the correct answer, but justify this answer not on the basis of independence but again, by saying that any of the sequences could happen, because, for example, “there are two sides and a 50/50 chance of getting any pattern.” On the Coins Sample Size item, while most students employed the Same A Same B line of thinking, there were, however, students who justified the response of “equally likely” with the 50/50 approach. In total, 58% of 5<sup>th</sup> graders, 47% of 7<sup>th</sup> graders, 44% of 9<sup>th</sup> graders, and 12% of 11<sup>th</sup> graders used the 50/50 Approach on at least two of the items. However, the results also show fluidity in students’ thinking, between using ratio thinking or the representativeness heuristic as well as the 50/50 approach. Although approximately half of all 5<sup>th</sup>, 7<sup>th</sup> and 9<sup>th</sup> graders used the 50/50 approach on at least two of the four items involving coins, very few students used the 50/50 approach across all four items: one 5<sup>th</sup> graders, two 7<sup>th</sup> graders, and three 9<sup>th</sup> graders. This prevalence among younger students calls for further investigation into the factors affecting development *out* of the 50/50 approach.

### Conclusions

Oftentimes in mathematics assessment, students are evaluated on the basis of their ability to provide the correct answer to a question. The findings of this study demonstrate that there are a variety of methods of arriving at such a correct answer: some methods are mathematically valid and others happen to produce the correct answer to that particular question but might become grossly inaccurate in other instances. For example, a student’s response that there is a 50% likelihood for two coins to result in one tails and one heads sounds flawless, but this study has shown that this same student could have arrived at such an estimate since he or she believes that *any* outcome of *any* number of coins has a 50% likelihood. This 50/50 approach, found to be quite common among students in grades 5 and 7 of this study, clearly deserves more attention. When does it take root among children? More importantly, when, why, and how does it fade away?

In terms of in-school assessment or national tests, what about the student who believes that this particular probability is  $1/3$ ? While this is an incorrect answer to

this question, this student is using the concept of a sample space, more sophisticated than the 50/50 approach. How do we as educators handle the issue of a wrong answer being more mathematically sophisticated than a right one given for incorrect reasons? Researchers and evaluators, and teachers too, need to examine the types of errors students make, which often stem from alternative student interpretations of the question itself. It is not enough for teachers to know that students perform poorly on a given task: knowledge of the common errors can help a teacher prepare activities that confront those errors or direct the students' attention toward the specificity of the language. As Konold (1993) writes, "Teachers become more effective as they increase their power to interpret student utterances, many of which may initially seem incomprehensible."

## THE PROBLEM SOLVING BEHAVIOR OF A MATHEMATICS MAJOR

Irene Bloom  
Arizona State University  
bloom@math.la.asu.edu

In the document *Principles and Standards for Teaching School Mathematics* (National Council of Teachers of Mathematics [NCTM], 2000), NCTM identifies Problem Solving as a major content strand for school mathematics. In addition, the Conference Board of the Mathematical Sciences (CBMS) recommends that “prospective teachers need to develop habits of the mind of a mathematical thinker” and need to be proficient problem solvers (CBMS, 2000). However, most undergraduate students have had more experience with “exercises” than they have with actual problem solving (Schoenfeld, 1985).

This study investigated the problem solving behaviors of Lee, a third year mathematics major intending to teach high school mathematics. He was enrolled in a capstone course geared toward the content areas taught in secondary schools. This course was taught from a “problem solving perspective.” That is, the class was exposed to a wide variety of problem solving situations from the full range of high school mathematics curriculum. Lee participated in two task-based interviews – one at the very beginning of the course and one at the very end. During those interviews, he was asked to solve three problems requiring knowledge of basic mathematical content and concepts such as basic geometry, algebra, proportions, and percents. Each interview began with the interviewer asking him to discuss his thinking and solution attempts as he worked on the problems. The interviewer observed his behaviors and periodically reminded him to verbalize his thinking and articulate a rationale for a specific behavior. The interviewer gave no indication regarding the correctness of the solution as the subject worked on the problems; however, she occasionally posed a question to promote greater articulation of his thinking and solution approach. The interviews also included periodic probing about his perceptions of his problem solving background and success.

The problem solving sessions were analyzed using the Four Phase Cyclic Problem Solving Framework (Carlson & Bloom, 2002, under review), which draws heavily on the work of Polya (Polya, 1945/1957) and Schoenfeld (Schoenfeld, 1985). One dimension decomposes the problem solving session into four phases of cognitive and metacognitive behaviors. These phases are Orienting (initial engagement with the problem), Planning (planning, strategizing, conjecturing, etc.), Executing (actual number and symbol manipulation and computation) and Checking (reflecting and checking). This dimension is very similar to Polya’s 4 steps (Polya, 1945/1957) but in our work with mathematicians, we found this to be an iterative process. Expe-

rienced problem solvers cycled through these phases until either the problem was solved or they gave up. The other dimension considers various aspects of problem solving. These aspects are Resources, Heuristics, Affect and Self-Monitoring. These categories differ slightly from Schoenfeld's framework (Schoenfeld, 1985). The heading of Affect is broader, and includes emotions and attitudes in addition to beliefs. Self-Monitoring refers only to the monitoring of products and processes during the course of the problem solving session. We include only monitoring and regulation from Schoenfeld's *Control* category since other aspects of control (e.g., regulating and planning) emerged in the global description of the problem solving process. These two broad dimensions (i.e., the cyclic phases and problem solving) interact at every level.

In this paper, I have used the framework to explore and characterize the problem solving behaviors of Lee at the beginning and end of the capstone course. The table below (see Table #1) provides a brief example of the preliminary analysis of the transcripts. In this excerpt, Lee is trying to solve the following problem: *Two numbers are "mirrors" if one can be obtained by reversing the order of the digits (i.e., 123 and 321 are mirrors). Find two mirrors whose product is 92565. Find two mirrors whose sum is 8768.*

In the initial problem solving session, Lee expressed concern about his level of content knowledge and his problem solving abilities. He worried that he was "slow" and didn't always "see" what he perceived his classmates did. But he also said that he liked math and felt satisfaction when he was able to solve a problem. His problem solving session revealed a deficiency in the use of metacognitive strategies. Lee appeared to struggle to make sense of the problems; hence much of his time was spent in the Orienting phase of the cycle. He tended to not verbalize a plan, and he was unlikely to check his progress for unreasonableness. He consistently looked to the interviewer for direction and reassurance during the actual problem solving. He revealed a low tolerance for frustration and admitted that with one problem, he would have given up if he were alone. However he was able to solve two of the three problems correctly, and the third problem would have been correct had he realized that he had not completed the problem as it was written.

Two things were particularly striking about this first interview. One was the inability to express what he was thinking. He appeared to go from organizing his information to solving the problem with no intermediate planning, yet some planning had to be taking place. It was as if he lacked the language to describe his thinking. The other interesting revelation was the fact that even though Lee was a math major and planned to teach high school math as a career, he was insecure about his abilities, both in the interview setting and during class sessions.

After a semester of extensive problem solving, explaining his reasoning both orally in class and in written assignments and being exposed to a wide variety of solution paths, he was interviewed again. He expressed and demonstrated greater confidence in both his problem solving ability and his content knowledge as well as and

Table 1.

| Excerpt   | Behavior                                  | Phase      |
|---|---|------------|
| Two numbers are mirrors if one can be obtained by reversing the order of the digits. Can you find two mirrors whose product 92,565?                 | <i>Initial engagement – reads problem</i> | Orienting  |
| No. [laughter]  | <i>Anxiety</i>                            |            |
| Two numbers whose sum is 8767.  | <i>Engagement – reads problem</i>         |            |
| I've seen this before.  | <i>Relates to previous problem</i>        |            |
| I don't even know where to start  | <i>Lack of confidence – confusion</i>     |            |
| If I have two numbers – do the mirrors, do they have to be like 4,5,6 and then 6,5,4 or can they be like 4,7,9 and 9,7,4? They can be that way too? | <i>Sense making</i>                       | Executing  |

| They're going to be obviously 4 digit numbers   | <i>Conjecture</i>                         | Planning   |
| what ever my second number here is will be my third number here-so automatically the one's got to go on that side if I have one here                | <i>Conjecture</i>                         |            |
| one's gotta go on the other side -- which would mean that this would have to be a seven. [mumble] this would have to be 5,                          | <i>Testing conjecture</i>                 | Executing  |
| , -- wait, that doesn't work.   | <i>Reflects on conjecture/work</i>        | Monitoring |

greater persistence in his work in general. "I feel pretty confident when I do a problem that I can see if my answer makes sense or not." He solved all three of the problems correctly. Unlike the first interview, he was regularly observed monitoring his progress, and he tended to rely on his own mathematical abilities to guide him through the problem rather than look to the interviewer for support. Lee was more accepting of his own solution paths after witnessing the variety of ways others solve problems. In the

second interview, he appeared to be more able to articulate his thinking process, especially in the planning phase of the problem solving cycle. The analysis also revealed a concern for the aesthetics of the solution (as in *nice*, as opposed to *ugly*). While this concern did not arise during the first problem solving session, Carlson noted in her work with professional mathematicians that they were regularly concerned with the aesthetics and quality of the solution – not just the correctness of it.

This study demonstrated the usefulness of the Four Phase Cyclic Problem Solving Framework as a tool for analyzing the problem solving behavior of students as well as mathematics professionals. The framework uncovered movement in Lee's use of self-monitoring during the problem solving process, his confidence in his problem solving ability, his ability to articulate his mathematical thinking and it helped to highlight an emerging concern for "nice" solution paths. Further research needs to be done to determine which aspects of the capstone course were the primary influences in the improvement he experienced, or if it was a combination of all the math courses he was taking.

**MAKING CONNECTIONS AND BUILDING ISOMORPHISMS:  
THE PROBLEM SOLVING OF TWO-YEAR COLLEGE  
STUDENTS AND YOUNG CHILDREN**

Barbara H. Glass  
Sussex County College & Rutgers University  
bglass1@att.net

Problem solving and justification of a diversified group of two-year college students were compared with approaches of younger pre-college students working on the same task. The students in this study were engaged in thoughtful mathematics. Both groups utilized similar strategies for their methods of justification and solution. They were able to make connections and build isomorphisms among the various problems. The findings support the importance of introducing rich problems to pre-college and college students, under particular conditions.

By the time students study mathematics at the college level, it is hoped that they would have developed an ability to reason effectively. At the same time, if previous mathematical learning were durable the college students would be able to apply the specific mathematical content that they have learned up to this point to new situations that they encounter. Unfortunately, many of the students have passed through their ten years of mathematics courses primarily in settings that emphasize rote and procedural learning. From a perspective of conceptualizing reasoning in terms of solving open-ended problems, it was of interest to learn whether students in a liberal-arts college mathematics course could be successful in making connections in a problem-solving based curriculum. Specifically, this paper reports on a study with community college students enrolled in liberal arts mathematics. It will describe, in the context of combinatorics (1) What connections, if any, are made to isomorphic problems and previous mathematical knowledge and (2) how college students' representations and level of reasoning contrast with those of younger children engaged in the same investigations.

### **Background**

Researchers at Rutgers University have documented children's thinking as they investigate problems in the area of combinatorics to determine how they think about the problems and justify their solutions (Maher & Martino, 1998; Maher & Speiser, 1997; Kiczek & Maher, 1998; Muter & Maher, 1998). One of these problems is the Towers Problem, which invites a student to determine how many different towers of a specified height can be built when selecting from two different color cubes, and to justify that all possibilities have been found. A second isomorphic problem, the Pizza Problem, invites a student to determine how many different pizzas can be created from a given number of toppings and to justify that all possibilities have been found. These tasks were given to the college students in this study during the problem-solving component of a liberal arts mathematics course.

### **Theoretical Framework**

The growth of mathematical knowledge is the process whereby a student constructs internal representations and connects these representations to each other. Understanding is the process of making connections between different pieces of internally represented knowledge or between existing internal connections and new knowledge. (Hiebert & Carpenter, 1992) Students build their understanding of concepts by building upon previous experience, not by imitating the actions of a teacher or being told what to do. (Maher, Davis, & Alston, 1991) Learners who first learn procedures without attaching meaning to them are less likely to develop well-connected conceptual knowledge. When students encounter new problems they are more likely to retrieve knowledge that is well connected than to retrieve loosely connected information. (Hiebert & Carpenter, 1992). The students in this study were encouraged to think about their solutions to problems, develop understanding of the mathematics and justify their answers.

### **Data Collection and Methodology**

Nine classes ranging in size from 6 to 25 students were studied from 1998 – 2000. Two groups from each class were videotaped as they worked on the Towers Problem and the Pizza Problem. Following the class sessions each student was required to submit a write-up of the problems. In addition, videotaped, tasked based, interviews of some of the students were conducted. From all the available videotaped data eleven students have been chosen for a case study analysis. Students were chosen to represent the range of the population that is included in the study. Videotapes of students selected for the case study have been transcribed, coded, and analyzed for methods of problem solving, methods of justification and connections that were made. The written work of these students has also been coded and analyzed. In addition, selected videotaped segments of other students have been analyzed.

The study was conducted at a small community college in a liberal arts mathematics course. The students spent approximately half of all class time working on various non-routine problems in a small group setting. The Towers Problem was given during the ninth week of the semester. The students began by working on towers that were four cubes tall. They then were asked to consider towers that were five cubes tall. Several groups also worked with towers where three different color cubes were available. The Pizza Problem was given during the fourteenth week of the semester. The students first worked on finding the number of pizzas that could be made if four toppings were available followed by the problem with five toppings. After solving the basic problem they were asked to consider the Pizza With Halves problem in which a topping could be placed on either a whole pizza or a half pizza.

### Results

Several of the college students noticed a relationship between the Towers Problem and the Pizza Problem. Three of these students were able to explain the isomorphism during the class session. Other students explained the isomorphism during task-based interviews. While working on the Pizza Problem most of the college students noticed the doubling pattern and used it to predict how many toppings would be needed to obtain one thousand twenty-four different combinations of pizza. The majority of these students also explained the reason for the doubling pattern that they had observed. Several students noticed the relationship between the pizza problem and the rows of Pascal's triangle and about half of these students were able to explain how the addition rule of Pascal's triangle related to pizzas. One student concurrently enrolled in a statistics course correctly used combinations to predict the number of pizzas. Several other students, who had previously learned about combinations, tried to calculate the number of pizzas using combinations. However, they did not understand combinations well enough to apply them to the problem correctly. These students attempted to do a single calculation to find the answer instead of doing separate calculations for each number of toppings that they could have on the pizza (Glass, 2001).

### Conclusions and Implications

The students in this study made connections and built isomorphisms among the problem solving tasks. Very few connections were made with previous mathematical knowledge acquired in a traditional lecture class, and most of these were trivial connections. Several students recognized that the problems could be solved by permutations or combinations, but demonstrated that they did not understand these concepts well enough to correctly apply them to the solution of novel problems. This would indicate that learning about mathematics in an atmosphere in which students are told what to do does not enable these students to develop genuine understanding. The students in this study demonstrated a high level of reasoning as they thought about the problems, justified their solutions, and made connections. They utilized strategies for solution and methods of justification and made connections similar to those of the students in the Rutgers University longitudinal study. While it cannot be disputed that the students in the longitudinal study benefited from exposure to rich mathematical experiences over an extended period of time, the students in this study, who had previously experienced a variety of traditional mathematics instruction, demonstrated that it is not too late to introduce rich mathematical experiences in a collegiate level mathematics class. The level of reasoning that these students demonstrated provides evidence that it is possible to experience thoughtful mathematics within a traditional fifteen-week semester. The findings support the importance of introducing rich problems to college students and giving them opportunities to work together toward a solution.

This research, based on the APOS Theory (Action-Process-Object-Schema) theoretical perspective, addresses the following questions: How can we describe the mental constructions that a student might make in order to develop his understanding of: (1) the concept of a Cartesian graph of a real function of one variable, given by an algebraic rule. (2) the concept of a real function defined by a vertical line test satisfying curve drawn in the Cartesian plane. During the presentation of this work we shall describe our theoretical analysis of the learning of these concepts articulating it with empirical data we have collected.

The function concept is one of the most fundamental notions developed in high school and beginning college mathematics courses. At the same time the teaching and learning of this concept have been considered most problematic. Evidence of the challenging aspects of its learning is amply supplied by the mathematics education literature. The question of how the function concept can be constructed by a student has been addressed by a few researchers, although issues related specifically to the graphical representation of functions in its cognitive construction facets have not been so much emphasized. When surveying the literature, we found that most of the work done in the area of graphical representation has focused on the consequences (performance, misconceptions) of the inner constructions already made by students. Much is still needed in the way of clarifying the nature of the mental constructions underlying the learning of the production of graphs of functions given by a formula and the inner construction of a function given graphically.

This study acquires its relevance from its connecting points with the function literature and from its focused line of interest in graphical representation. The use of this representation as a supporting intuitive foundation in the introduction of definitions, properties, theorems and algorithms in mathematics, in particular in Calculus, has been debated for efficiency. What are students really “seeing” when we rely on graphs to introduce ideas of limits, continuity, derivatives and integrals? Moreover, the mental construction of functions given only by a graph seems fundamental by its relation to frequently mentioned problems related to the development of the function concept. When dealing with functions given only by graphs students have to confront their bias toward the presence of a formula and they also confront their desire for regularity of graphs or causality of functional correspondences. We also consider this

environment a fruitful grounding to develop the symbolic language of mathematical functions.

The question we address in this research is the following: How can we describe the mental constructions that a student might make in order to develop his understanding of: (1) the concept of a Cartesian graph of a real function of one variable, given by an algebraic rule. (2) the concept of a real function defined by a vertical line test satisfying curve drawn in the Cartesian plane (no given formula). Furthermore, we would like to enhance our understanding of how these constructions might be made by the learner, which might be the difficulties he finds in this process and which sort of activities might potentially engender these constructions.

This research is based on the theoretical perspective known as APOS Theory (Action-Process-Object-Schema). According to this theory, understanding a mathematical concept begins with manipulating previously constructed mental or physical objects to form actions; actions are then interiorized to form processes which are then encapsulated to form objects. Objects can be de-encapsulated back to the processes from which they were formed. Finally, processes and objects can be organized in schemas (Asiala et al., 1996).

This work was conducted in Rio de Janeiro, Brazil, and its participants comprised 115 first semester college students enrolled in a course entitled Introduction to Calculus and 15 high school mathematics teachers registered on in-service activities. The research was carried on according to the following methodology: as a starting step we made an initial theoretical analysis in order to propose a genetic decomposition, or model of cognition, of each concept under study; that is, a description of the mental constructions (actions, processes and objects) a student might make in order to develop his understanding of each one. This preliminary genetic decomposition was used to study students' and teachers' understanding of the same concepts through the analysis of their responses to a written inventory (set of problems) with follow-up taped interviews. The collected data was analyzed by a careful articulation with our initial genetic decomposition and relevant literature. Finally the result of this analysis led to the formulation of a revised version of our initial genetic decomposition to reflect the empirical data. This new version of our model of cognition of the two concepts will be exposed at the presentation of this work when we shall also exhibit subjects' written and oral work. In addition, we will describe our inventory problems, discuss their adequacy to elicit appropriate data for this investigation, make suggestions for pedagogical strategies and point out future studies.

We can easily see that there is no uniformity in graph representation in books and classrooms, and although some may be more suitable to support certain reasoning, students do not seem to move easily among them. Even in relation to a simple thing as representing a point belonging to a graph, it appears that there is a cognitive difference between conceptualizing the representation of a point of a function graph as the

crossing of two lines or as the end point of a vertical segment. The former seems to be more related to an action conception and the latter to a process one.

The idea that to construct a graph of a function it is enough to know some of its values is frequently observed. This misconception is firmly rooted and hard to modify. When high school students are introduced to graphs of affine and quadratic functions they are told that these graphs consist of lines and parabolas, often with no justification. And what is worse and more problematic, teachers may think that there is no need for justification of these assertions which they consider self-evident. Many teachers do not seem aware that when they draw some graphs they choose a “good” table and join the points using what they already know about the function behavior. Beginning students have no way to discriminate between bad or good tables and no reason to join the points the “right” way.

The interpretation of the construction of graphs of  $f(ax + b)$ , knowing the graph of  $f$ , as a result of an action on the graph of  $f$  leads to lots of misunderstandings by the students. The necessary discrimination between “shifts – distance preserving – rigid curve” and “stretch – not distance preserving – rubber band” is hard even to learn only “how to do” those sort of tasks. The understanding of these constructions, one that goes beyond strategic memorization, seems to require a difficult coordination among actions and processes in different settings - numerical, graphical, symbolic, tabular and algebraic - and a conceptualization of the graph as a set of points.

APOS Theory was very useful to reason about, explain and synthesize the observable behaviors of the subjects involved in this investigation as they performed the proposed tasks.

## **GENERALIZATION PROCESSES IN COMBINATORIAL PROBLEM-SOLVING SITUATIONS**

Bharath Sriraman  
University of Montana  
b\_sriraman@yahoo.com

The process of generalization is an important component of mathematical ability, and to develop this ability is an objective of mathematics teaching and learning. In this research study problem-solving strategies and behaviors of nine high school freshmen in combinatorial problem-solving items were documented with the purpose of identifying strategies and behaviors that fostered the formation of generalizations. Frank Lester's (1985) problem-solving model was adapted in order to classify student problem-solving behaviors. The generality that characterized the problem-solving items was the pigeonhole principle. Four of the nine students were successful in discovering the pigeonhole principle. The findings indicated that students who were able to generalize focused on understanding the structure of a given problem as well as engaged in reflective abstraction, in addition to being motivated and highly curious.

### **Introduction**

The National Council of Teachers of Mathematics (NCTM, 2000) calls for mathematics instructional programs that allow students to become sophisticated with mathematical processes like problem solving, representation and reasoning as well as opportunities to reflect on and monitor their work, which lead to greater abstraction and a capability for generalization. Mathematics education research on generalization has focused on elementary school children's abilities to generalize number concepts (Dienes, 1961; Davydov, 1990), and generalizations made by students in arithmetic and algebra (Krutetskii, 1976). There is lack of research on generalization in the context of problem solving at the high school level. As a practicing high school teacher, the focus of the researcher was on understanding the nature of generalization processes used by high school students in problem-solving situations. The particular research questions were as follows:

1. What are the mathematical experiences that enable students to generalize?
2. When engaged in problem solving, how do students discover generalizations that characterize a class of seemingly different problem situations?
3. How can high school teachers create mathematical experiences that foster abstraction and generalization?

### **Methodology**

Students in a ninth grade algebra class taught by the researcher were assigned five non-routine combinatorial problems in their journals, at increasing level of complexity. The pigeonhole principle could be applied to solve each of the five problems. The

researcher hoped that some of the students would eventually be able to discover this general principle by discerning similarities in the structure of the problems and their solutions. The data for this study was collected through students' journal writings, clinical interviews and the teachers' journal writings. The interviews were open-ended with the purpose of getting students to elicit their thought processes in solving a given problem. In all, five rounds of interviews were conducted with the nine students over a three month period. The researcher/teacher documented the evolving strategies of the students and classified them according to Lester's (1985) problem solving model, which consists of four categories. *Orientation* refers to strategic behavior to assess and understand a problem. It includes comprehension strategies, analysis of information, initial and subsequent representation, and assessment of level of difficulty and chance of success. *Organization* refers to identification of goals, global planning, and local planning. The category of *execution* refers to regulation of behavior to conform to plans. It includes performance of local actions, monitoring progress and consistency of local plans, and trade-off decisions (speed vs. accuracy). Finally, *verification* consists of evaluating decisions made and evaluating the outcomes of the executed plans.

Data gathered through journal writings, open-ended interviews and classroom observations was analyzed using techniques from grounded theory (Glaser & Strauss, 1977). Lester's (1985) model was operationalized in order to code data and to identify variables related to successful and unsuccessful generalization strategies.

### **Findings and Implications**

Four students were successful in discovering, verbalizing, and in one case successfully applying the generality that characterized the solutions of the five problems, whereas five students were unable to discover the hidden generality. Two new categories emerged as the result of adapting Lester's (1985) model, namely *generalization*, and *reflection*. *Generalization* was characterized as the process via which students identified commonalities in the structure of the problems and their solutions. It included making analogies as well as specializing from a given set of objects to a smaller one. *Reflection* in this study was characterized as the process by which the student abstracted knowledge from actions performed on the problems. In other words reflection consisted of thinking about similarities in the problems and solutions, and abstracting these similarities over an extended time period.

The results indicate that generalization is a complex process and not very many students are able to discover and formulate them on their own. The students that were successful showed a high level of reflection in addition to concern with orientation and organization in a problem-solving situation. They displayed conceptual understanding because they were able to abstract similarities through reflection (Dubinsky, 1991) and form valid conceptual links (Hiebert, 1986; Skemp, 1986). Affect played a role in how they approached a problem situation. In particular their beliefs about what constituted mathematics influenced how they tackled a given problem. This leads to the question

of whether generalizations can be taught? Can beliefs be changed? Can reflection be taught?

The first and foremost challenge for high school teachers is to find various classes of problems which have general solutions, that are accessible to the students and which capture their interest. Hence, the pedagogical focus of the teacher should be on understanding the mathematical structure of the problem as opposed to simply solving it. The study indicated that one of the variables that contributed to students being unsuccessful in forming generalizations was the obsession to execute, verify (often incorrectly) without having an understanding of the underlying assumptions (orientation) and poor global planning (organization). The point here is not to simply pose problems for problem solving, instead the problems should be used to lead students to think mathematically, to engage all of the students in the class in making and testing mathematical hypotheses similar to what mathematicians do.

The results indicated that reflective behavior on the part of the student contributed to forming generalizations. Many of the students who were unsuccessful in forming generalizations claimed to have “looked back (reflected)” by checking that they had utilized all the information given in a problem. In spite of this they either formed false or no generalizations. Many of these students had been “taught” Polya’s (1945) four-step approach to problem solving at some point in the middle school curriculum in a manner akin to learning a procedure. However there is a big distinction between the “looking back (reflecting)” to make sure that the given information was somehow utilized in the solution, as opposed to reflecting to abstract similarities in the underlying structure of the problems and solutions. Such reflective behavior might be very hard to teach. Interestingly enough the students who engaged in a great deal of reflective behavior often characterized mathematics as “a way of thinking.” So one possible way of making students engage in reflective behavior is by first trying to impact student beliefs about mathematics.

## UNDERSTANDING NOVICE TEACHERS: CONTRASTING CASES

Jeffrey E. Barrett, Graham A. Jones, Edward S. Mooney,  
Carol A. Thornton, JoAnn Cady & Jo Olson  
Illinois State University  
jbarrett@ilstu.edu

Tricia Guinee  
Peoria School District, Illinois

This study examined the classroom practice and beliefs of two novice teachers, Anne and Rachel, during the first year of their involvement in Project PRIME, a district-wide development program. Using accounts of practice (Simon & Tzur, 1999), the professional developer interviewed and observed the two novice teachers throughout the school year and established a hypothetical learning trajectory as part of their professional development. By the end of the first year, neither teacher's classroom practice reflected the goals of PRIME: using worthwhile mathematical tasks, questioning and promoting student's thinking. However, their practice was observably different and so were their beliefs about teaching. Anne's practice was consistent with the literature's characterization of a novice teacher, while Rachel's aligned more with that of a veteran teacher. These differences between these novice teachers proved to be an on-going challenge for professional development.

A number of studies have addressed the beliefs and classroom practices of novice teachers (Borko et al., 1992; Leinhardt, 1989; Leinhardt & Greeno, 1986; Shealy, 1995; Shealy, 1994; Sherin & Drake, 2000). These studies define *novice* teacher as one with less than 3 years of teaching experience and one whose teaching tends to focus on "survival" (Miles & Huberman, 1994) and establishing basic classroom routines (Sherin & Drake, 2000). Most of the abovementioned studies have focused on novice teachers who have come directly from high school into pre-service teacher education programs. Hence, these studies may have produced characterizations of novice teachers that do not necessarily hold up for more mature-aged novice teachers. In this research, we bring a different perspective by comparing two novice teachers who brought contrasting experiences to their early years of teaching. More specifically, our study asked the following question: What were the beliefs and classroom mathematical practices of two novice elementary teachers during the first year of a professional development program?

### Theoretical Orientation

The professional development program that served as the context for this study was Project PRIME (Thornton & Barrett, 2000), a systemic effort that focuses on enhancing the practice of elementary teachers working in a mid-size urban school district with a high minority student population. The key elements of PRIME are

improving teachers' pedagogy and providing classroom-based support to facilitate implementation of a reform-based curriculum (TERC, 1998). More specifically we aim at enhancing teachers' development of three integrated instructional strategies: (a) posing worthwhile mathematical tasks, (b) asking responsive questions, and (c) listening to students' responses and promoting their thinking and engagement.

*Accounts of practice* (Simon & Tzur, 1999) provided the theoretical infrastructure for the case-study analysis of the two novice teachers in this study. Simon and Tzur describe accounts of practice as an approach for understanding teachers' current practice and as a means of viewing their current practice in the context of professional development programs that embrace envisioned reforms. Research that uses accounts of practice has two key elements: (a) the development of a conceptual frame, and (b) the use of the conceptual frame to trace teachers' classroom practice. The conceptual frame should be based on research in mathematics education and the particular perspectives and concerns of the researchers as they relate to the professional development project. The conceptual frame or lens in our study was based on PRIME'S three instructional strategies. We used these strategies as a lens to observe teachers' practice and beliefs. Using accounts of practice also provided an opportunity to ascertain why the teachers taught as they did.

The multifaceted nature of the accounts of practice methodology made it very appropriate for driving the collection of data to address the research question for this study. More specifically, we were able to use the conceptual frame to trace and interpret the teachers' beliefs and classroom mathematical practices captured through videotape and interview.

### **Method and Setting**

The design for this study was in accord with the "accounts of practice" methodology (Simon & Tzur, 1999). We used case-study analysis to examine the beliefs and classroom practices of two novice teachers during the first year of PRIME.

### **Participants**

The two novice teachers in this study were part of a pool of 337 teachers who agreed to participate in the 3 years of PRIME. These novice teachers, identified by pseudonyms, were also part of a random sample of 16 teachers selected for detailed case-study analysis. Both novice teachers were teaching Grade 1 classes. *Rachel*, a novice teacher in her first year of teaching, came into teacher education after having 20 years in the workforce. She taught for 1 year as a full-time teacher-aide prior to obtaining a teaching position. *Anne* had entered her teacher education program immediately following high school and was in her first year of teaching.

### **Procedure**

During the PRIME summer workshop, prior to the first year of the program, the two teachers undertook a 1-week program that focused on ways that geometric con-

cepts can be built using tasks from *Investigations in Number, Data, and Space* (TERC, 1998). These TERC materials used by these two teachers were intended to support and enhance their mathematics curriculum in the coming years.

Working in collaboration with the second-named author, the first-named author wrote accounts of the teachers' classroom practice and beliefs during the fall and spring semesters. These accounts served as the basis for generating hypothetical learning trajectories (HLTs); that is, determining a plan, identifying activities, and conjecturing the way the teacher development process might go. We engaged teachers in a sequence of activities intended to highlight the relationship between mathematical tasks (like those contained in the TERC materials) and children's subsequent understandings.

### Data Sources and Analysis

Data were gathered from four sources: (a) video tapes of two teaching sessions for each teacher, one in the fall and one in the spring; (b) detailed field notes of six teaching sessions during the intervention; (c) field notes of interviews associated with the six teaching sessions in each semester (two groups of three consecutive days); and (d) samples of students' work. Using a modification of Miles and Huberman's three-part analysis (1994), we used a double-coding procedure to analyze the video and field data in terms of the conceptual frame: PRIME's three integrated instructional strategies. The use of four sources of data and the generation of independent summaries and codes allowed for triangulation of the data in the sense that it enabled both confirming and alternative interpretations.

## Results

### Classroom Practices

Using the PRIME instructional strategies as a lens, the classroom practices of the two target teachers were analyzed during the first year of the program. The thick descriptors of Anne and Rachel's classroom practice are presented in Table 1.

With respect to *worthwhile mathematical tasks*, the outward manifestation of these two teachers' practice was similar: their students did not experience the TERC tasks in the way they were intended. Both teachers reduced the tasks to a sequence of simpler tasks. However, the teachers worked in different ways.

Anne gave her students' the opportunity to solve the problem but when the children reported she either left them hanging without feedback or led them inextricably to her solution. For example, near the end of the first year of the project, she posed this question: "Draw a cake in the shape of a rectangle and indicate how you and I could share it." The task was meaningful to the children, they seemed to understand that share implied *divide equally*, and the task had the potential to build understanding of mathematical concepts as well as to make connections between number and space. However, as we will see below, Anne did not use the children's responses to optimize the potential for the task.

**Table 1.** Classroom Practices

| PRIME Strategies                           | Anne  | Rachel  |
|--|---|---|
| Worthwhile mathematical tasks              | She is willing to let the children engage in thinking about worthwhile tasks, but lacks the confidence to implement her intent. | She demonstrates a steadfast resolve to reduce any worthwhile task to a procedural task that she can model for the children.  |
| Questioning                                | Asks children to describe their solutions but rather than delve into their thinking leads them to her predetermined answer.     | Her questions focus on checking that children use the correct procedure; she often seeks a response from the whole class to reinforce the procedure.                  |
| Listening and promoting students' thinking | She allows them to express their ideas; however, she does not feel comfortable analyzing and extending children's thinking      | She assesses responses according to whether or not they follow her model; seldom seeks explanations as she sees the role of elaborating responses as her prerogative. |

By way of contrast, Rachel broke the task into subtasks or more accurately subroutines that reduced the cognitive load of the problem. She often reminded the children of some of the procedures that had previously been established for solving problems like the one she was about to give. For example, near the end of the first year of the project she asked the students, "Which is longer than 2 inches, your fingernail or your hand?" Rather than let the children explore or even think about the task, Rachel immediately told them to look at their ruler, find 2 inches, and compare. Consequently the task was immediately reduced to a set of predetermined procedures that were not necessarily part of the children's mathematics.

With respect to *questioning*, Anne reflected what Brousseau (1992) calls the *Jourdain effect* (p. 20). By the Jourdain effect, Brousseau refers to a situation where the

teacher avoids having a discussion about knowledge with the student and instead recognizes a response of the students that has been stripped of meaning. In our situation, Anne started with open questions, encouraged students to convey their own meaning, but then avoided any follow-up discussion on the children's knowledge. The following dialogue in the cake-sharing example typifies Anne's Jourdain approach.

Anne: How could the cake be shared between you and me? Do it in your own way and be ready to tell me about it.

[Anne walked around while the students solved the problem, but did not question any students. Her only interaction was to remind one student that a rectangle was long "like a square but long."]

Anne [After about 3 minutes]: What are you looking for in this problem?

Children [In unison]: Two equal parts

Anne: And equal parts mean they're the...

Children [In unison]: Same

Anne: So, you cut it down the middle.

In spite of the fact that students had valid solutions with horizontal cuts, vertical cuts, and diagonal cuts, Anne did not pick up on these solutions in the dialogue. Even though she must have seen them she simply asked the students questions about equal parts when it was obvious that many of them had gone well beyond that level of understanding and had rich solutions to share.

By way of contrast, Rachel epitomized Brousseau's (1992) *Topaze-style*. That is, she used an instructional approach in which the students' response to a question is determined in advance and the teacher negotiates the conditions under which the response is produced. The following dialogue for the fingernail-hand problem was typical of her questioning:

Rachel: Who can tell me? Which is longer than 2 inches, your fingernail or your hand?

Student 1: Your fingernail.

Rachel: What do you think? [pointing to another child]

Student 2: Your hand.

Rachel: Your hand, that is correct. Why?

Rachel [without waiting for the children]: Because how big is an inch? Who can show me an inch?

Many children held their hands a foot apart, and were individually corrected. However, by now the original question had become submerged, marooned by a sea

of subroutines. In essence, Rachel's questions were not predicated on doing problem solving but on checking the various subroutines she had prescribed in advance.

With respect to *listening to and promoting students' thinking*, both teachers ultimately assessed children's responses against their own established standard. Using a Jourdain approach, Anne encouraged children to generate different representations but did not feel comfortable asking the children for explanations especially when a child was going in a direction different from the teachers' own solution. Rachel's Topaze-like strategy was clear from the outset: if the child's solution was correct (fitted her solution), she elaborated and explicated the student's solution; if the child's solution was incorrect, Rachel asked another child or represented her model without further discourse with the child.

In an overall sense Anne's classroom practice was often different from what she intended; that is, it was different from her professed intent to meet PRIME goals. By way of contrast Rachel's practice was consistent with "her" intent and she had already established the routines to meet her goals. Notwithstanding these differences, the end product of their classroom practice was much the same and was clearly inconsistent with the direction of the PRIME Project and the intent of the TERC (1998) resources.

### **Beliefs**

The teachers' beliefs were identified during interviews with the first researcher. These interviews were undertaken as part of the accounts of practice methodology. Some of these beliefs arose in response to questions; others were volunteered by the teachers during discussion. The key beliefs identified for Anne and Rachel are listed in Table 2.

The beliefs of Anne and Rachel provide the essence of their classroom practice. Anne understands the key tenets of PRIME and is able to articulate them. She believes that children will produce different mathematical representations for problems and she thinks these representations may be helpful for instruction. However, she professes a lack of confidence in her own mathematics and this is reflected in her beliefs about children's mathematical thinking and her reluctance to use children's solutions to enable sense-making and the building of mathematical knowledge. By way of contrast, Rachel's beliefs seem to be more firmly held and her beliefs are consonant with her classroom practice. She is quite definite that children can't act mathematically on their own and as a consequence teachers must demonstrate the correct mathematical procedure and then ensure that children adopt the teacher's procedure. Rachel is steadfast in her belief that learning for "important" written tests and chapter tests will not occur through any other mechanism.

### **Discussion and Conclusions**

This study examined the classroom practice and beliefs of two novice teachers during their first year of teaching and the first year of a professional development

Table 2. Beliefs

| Anne   | Rachel   |
|--|--|
| Children will use different representations that may be helpful for instruction.                                     | Children are unable to do mathematics independently of the teacher.  |
| I have trouble constructing mathematical ideas; hence, my students will not be able to construct mathematical ideas. | Children learn math when I demonstrate the procedure that are to imitate.                                    |
| Children will produce different solutions and representations but the textbook solution is the ultimate authority.   | Children should produce the teachers' model solution; multiple solutions are likely to confuse the children. |

program that had been adopted by their school district. The end product of each novice teacher's classroom practice was similar but they reached these states in different ways. From the perspective of the first two PRIME goals, Anne's classroom practice showed potential in that her mathematical tasks were often worthwhile and her initial questions opened up children's thinking. However, she lacked the confidence to use students' thinking to engage them in mathematical sense-making. In essence, Anne's practice was in direct contrast with her espoused beliefs that were consistent with PRIME instructional goals. In an overall sense, Anne's classroom teaching reflected that of a *novice* teacher in that her actions were consistent with the literature on novice teachers: specific goals not carried through (Sherin & Drake, 2000); frequent confusion caused by mis-sent signals (Leinhardt, 1989); struggles to listen to children's thinking (Fennema & Franke, 1992); dissonance between beliefs and practice (Cooney & Shealy, 1997); and lacking confidence in her own mathematics (Ball, 1990).

By way of contrast, Rachel's practice was deliberate and she was completely in control of an approach that seemed to be built on well-established routines, albeit routines that were not consistent with PRIME or reform directions in mathematics teaching. Rachel consistently reduced the cognitive load of worthwhile mathematical tasks, used Topaze-leading (Brousseau, 1992) when she questioned students, and assessed students' responses according to their fit with her own predetermined norm. Nevertheless, Rachel's classroom teaching tended to reflect that of a *veteran* teacher in that many of her actions were consistent with the veteran teachers literature: transparent system of goals (Leinhardt, 1989); detailed agenda and well established routines (Leinhardt & Greeno, 1986); minimal student confusion about what was required

of them (Leinhardt, 1989); and beliefs that were consonant with practice (Cooney & Shealy, 1997). Consequently, even though Anne and Rachel were both *novice* teachers they brought very different beliefs and actions to instruction, and these differences proved to be an-going challenge for the professional developer.

In accord with the ongoing cycle associated with *accounts of practice* (Simon & Tzur, 1999), we are refining the hypothetical learning trajectory for both teachers as we move into the second year of PRIME. Although we still intend to have both teachers focus on children's learning as their key goal, the activities and conjectured learning processes for each will be different. For Anne, the thinking of the students was distracting, confusing, and even anxiety building. Hence, we believe that she needs to be guided to study and discuss pertinent examples from her students' solutions, statements and questions. For Rachel, there is no evidence that she believes children are capable of building their own mathematical solutions. Hence we are intending to video tape the PD working with her class on open-ended problems that produce samples of children's work. Rachel and the PD will observe these videotapes together and analyze the children's work before any further attempt is made to have her adopt an approach to teaching that promotes mathematical sense making.

In this research report we share results of a study of the use of an adaptation of Lesson Study, a form of professional development typically used in Japanese elementary schools, with secondary mathematics teachers in the United States. We draw on Tharp and Gallimore's (1998) framework of "assisted performance" to present our analysis of the activities of a lesson study group (LSG). We describe the activities of the LSG and then use five characteristics of good assistance activities as an organizational frame for an analysis of the quality of the activities: mutual respect and trust; inter-subjectivity; responsiveness; joint projective activity; and reciprocity (Brown, Stein, & Forman, 1996). We found that these five characteristics were present in the activities of the LSG as participants planned, taught, and reflected on lessons intended to help students understand the process of finding sums of infinite geometric series. We provide examples of how the five characteristics interacted to make this a powerful professional development activity for not only the two teachers but also other participants in the LSG.

Many teachers and providers of professional development in the U. S. have become interested in Lesson Study, a form of professional development typically used in Japanese elementary schools (Stigler & Hiebert, 1998). In Japan, *research lesson* or *study lesson* refers to lessons that teachers jointly plan, observe and discuss. The same two words in the reverse order, *lesson research* or *lesson study*, refer to an instructional improvement process of which the research lesson is the heart (Lewis, 2000). When a Japanese school engages in *Lesson Study*, teachers form *Lesson Study Groups* (LSGs). (See Lewis, 2000 for an extended discussion of LSGs and the process of Lesson Study.)

In this research report, we share some results of the use of an adaptation of Lesson Study with secondary mathematics teachers. The research was conducted as part of a professional development project entitled Collaboration for Enhancing Mathematics Instruction (CEMI), funded by Lucent Technologies Foundation. CEMI lesson studies are conducted in LSGs consisting of middle and high school mathematics teachers, university mathematicians, university mathematics educators, and pre-service secondary mathematics teachers. The CEMI participants have met as a large group and in

their smaller LSGs since all 2000. We report on the activities of one LSG during the spring of 2001. The CEMI project is not trying simply to engage U. S. secondary mathematics teachers in Japanese lesson studies, but rather to adapt this model of professional development for several purposes. These include providing professional development for all of the participants in the project and creating an extensive community of people with diverse perspectives but the common goal of providing secondary students with quality mathematics education. The research component of the project seeks to understand these activities and their impact on the participants and the participants' classroom teaching.

This research report presents an analysis of the activities of one lesson study group in which two experienced teachers, Ms. JP and Mr. KB participated. Using aspects of Tharp and Gallimore's (1998) model of learning as movement from assisted performance to unassisted performance through a Zone of Proximal Development (ZPD), we analyze the activity settings of the lesson study group in which the two teachers were engaged and the characteristics of those activity settings.

### **The Framework of Assistance**

In *Rousing Minds to Life: Teaching, Learning, and Schooling in Social Context*, Tharp and Gallimore (1998) propose a theory of teaching that they characterize as "teaching as assisted performance." Anchored in Vygotsky's theory of the ZPD and also in the concept that formal learning/teaching should resemble informal learning/teaching, Tharp and Gallimore's (re)definition of teaching offers teachers and educational researchers a lens through which to view teaching and teacher learning. As part of the framework, Tharp and Gallimore propose that learning occurs in *activity settings* and that those settings can form units of analysis that support deep understanding of the social context of assisted performance. They theorize that assisted performance does not occur randomly, nor do the activity settings that support assisted performance. Instead, they argue, assisted performance only occurs in the context of goal-directed action.

### **The Five W's**

Attending to the "famous five W's can assist us here as an outline for considering the interlocked dimensions of activity settings" (Tharp & Gallimore, p. 74). A brief discussion of the 'who,' 'what,' 'when,' 'where,' and 'why' of activity settings is presented here.

In analysis of activity settings, the 'who' refers to those people who are present. Tharp and Gallimore propose that those people are not there by accident, and that each person contributes uniquely to the activity setting. Analysis of the 'who' of an activity setting serves to help define the setting as well as assisting in an explanation of possible differences between settings.

Similarly, the 'what' of activity settings further helps to define the setting. Col-

lecting data pertaining to the 'what' of activity settings and the resulting analysis of those data should include two dimensions: operations (what is done) and scripts (how the operations are done).

Because "activity settings cannot exist without time" (p. 76), the 'when' of those settings is important to include in any analysis. Are the activity settings scheduled at a time conducive to assisting performance? Is enough time allotted for assisting performance? How do the participants utilize the time they have in activity settings?

The 'where' of a particular activity setting deepens our understanding of a specific activity setting on a holistic level, as well as providing data that could be used to support differences between settings. Is the space appropriate and conducive to learning? Are there sufficient resources available?

While the first four of the "famous five Ws" provide contextual data about activity settings, the 'why' of the activity setting is perhaps the most important aspect of analysis as it is the least controllable aspect of any activity setting. Tharp and Gallimore argue that there are two facets of 'why' that must be attended to: the *motivation* and the *meaning*. What motivates the 'who' to be involved? What meaning and understanding of the activity do the participants hold?

Tharp and Gallimore argue that utilizing a combination of these five components during analysis allows us to 'know' an activity setting on a deeper level. Further, they argue, if we wish to design "a school organization in which assisted performance occurs at all levels, *the task is to create activity settings*" (p. 80; italics in original). We argue that the same condition holds for organizing professional development experiences.

### Characteristics of Assistance

The assistance provided during activity settings can be analyzed further. The following five characteristics of good assistance activities are suggested by Tharp and Gallimore's work and provide an organizational frame for our analysis: mutual respect and trust; intersubjectivity; responsiveness; joint projective activity; and reciprocity (Brown, Stein, & Forman, 1996). These are briefly described below.

#### Mutual Respect and Trust

The establishment of mutual respect and trust is an essential component of any assistance relationship (Hamann, 1992). That is, both the assistor and the assisted must respect each other and trust that each has good intentions. For teachers to make their teaching public for comment, as happens in a lesson study, respect and trust are paramount.

#### Intersubjectivity

Equally important is that the members of the LSG achieve some measure of intersubjectivity. That is, the development of common understanding of the purposes

and meanings of the activity and the language to use in it are critical. Also, the joint engagement in cognitive strategies and problem solving are aspects of interaction that influence each participant in an assistance activity.

### **Responsiveness**

“Assistance is best when it is contingent on and responsive to learners’ level of proficiency and perceived need” (Brown et al., 1996, p. 70). Within the activities of an LSG, both the topic of the work must be seen as important and the assistance provided must take into account both the mathematical and pedagogical proficiencies of the participants. Because of the diversity of the LSG members’ experiences and needs, this characteristic may be particularly difficult to achieve.

### **Joint Productive Activity**

“It is also important that assistance be provided in the context of joint productive activity” (Brown et al., 1996, p. 71) which involves working together on an authentic task that is directed toward the accomplishment of a clear, jointly constructed and recognized outcome. The characteristic of having a specified and valued product toward which the members collaboratively work seems to be somewhat rare in the work of educators.

### **Reciprocity**

“The joint productive nature of good assistance increases the possibility that the assistance activity might have another necessary characteristic, reciprocity” (Brown et al., 1996, p. 71). Each member of an LSG should benefit from the group’s activity in some way and no member should feel they are working but not getting value from the work. This is in contrast to many professional development activities in which the teachers are the receivers of something they don’t value from an outside expert who does not expect to benefit from the activities (other than monetarily).

### **Context and Methodology**

The data used for this report were collected in the spring semester of 2001 and are data on one of three Lesson Study Groups active during that semester. We will call this LSG1. In February 2001, all the teachers and mathematics educators participating in the CEMI project met to decide on an overarching theme for the semester’s lesson studies. It was determined that every group would try to pay particular attention to those aspects of teaching and learning emphasized in the Connection and Communication standards of the National Council of Teachers of Mathematics’ (NCTM) *Principles and Standards for School Mathematics* (NCTM, 2000). Each LSG was to determine the topic of its lesson study and the scheduling of both LSG meetings and the teaching. The members of LSG1 were two in-service secondary mathematics teachers, Mr. KB and Ms JP; two pre-service secondary mathematics teachers, Ms EB and Ms JD; one university mathematician, Dr. CY; one mathematics education profes-

sor, Dr. PK; and two mathematics education doctoral students, Ms AK and Mr. YK. LSG1 members engaged in the following activities:

Audiotapes were transcribed and transcripts were verified for accuracy, often by using the related video tapes. Data were divided into four subsets corresponding to four subsets of activities that we identified: planning (first four activities); implementation and reflection in Mr. KB's classes (next four activities); implementation and reflection in Ms. JP's class (next two activities); and sharing LSG1 work with others (next two activities). The ILF data contributed to each of the four subsets. One level

of analysis consisted of coding each of the four subsets of data for information that would allow us to describe each activity using the “five W’s” as Tharp and Gallimore suggest. Another level of analysis involved coding each subset of data using the five characteristics of good assistance activities: mutual respect and trust; intersubjectivity; responsiveness; joint projective activity; and reciprocity to determine the extent to which each of these were present in the activities of LSG1. This coding work was divided among the authors. After the initial coding was completed, the authors met to discuss the results of the coding and to reach consensus on any pieces of data that seemed problematic. We then discussed the patterns we found in the data coded and agreed on general themes that are reported in this paper. There is much more that could be said about the activities of LSG1 during this brief period, but we lack the space here to report that.

### **The LSG Activities**

We first use the “five W’s” to describe the activities of LSG1. Our purpose here is to provide the reader with some understanding of the LSG’s activities, but we can not be comprehensive in our description here. We begin by providing an overview of the lesson study cycle in which the group engaged and then proceed to describe each subset of activities in more detail. The members of LSG1 decided in their first planning meeting that they would develop a lesson or lessons that could be taught in the Algebra II classes of both Mr. KB and Ms. JP’s. They met four times to plan these lessons, meeting in the classroom of either Mr. KB or Ms. JP so that they would have access to the materials available in those schools. Between planning meetings, members worked alone or in smaller groups and there was some correspondence and lesson plan writing done using a web site with space designed for that purpose, the Inquiry Learning Forum ([www.ilf.crlt.indiana.edu](http://www.ilf.crlt.indiana.edu)). The lesson was first taught in Mr. KB’s class and required two class 48-minute periods. Mr. KB taught and most of the group members observed. Immediately following the instruction, the group met to discuss the lesson and revise their plans. Ms. JP then taught the lesson in one 85-minute class period and the group met immediately after to discuss and revise the lesson. About two weeks after the lesson study concluded, all participants in the three LSGs met together in two 2-hour sessions to share the work of all three LSGs. About five months after teaching the lesson, Mr. KB and Ms. JP presented their lesson at a state meeting of mathematics teachers.

### **Planning**

As noted earlier, the members of LSG1 were two in-service secondary mathematics teachers, Mr. KB and Ms. JP; two pre-service secondary mathematics teachers, Ms. EB and Ms. JD; one university mathematician, Dr. CY; one mathematics education professor, Dr. PK; and two mathematics education doctoral students, Ms. AK and Mr. YK. All were involved in the lesson planning process. The in-service teachers

were teaching mathematics in different high schools. The pre-service teachers were enrolled in the secondary mathematics teacher education program at the local university. The mathematics educators and the university mathematician were from the same university. All the participants voluntarily participated in the lesson planning process. Although one of the mathematics educators and the mathematician were faculty members at the university, neither was an instructor of the two pre-service teachers at the time of the study. The LSG1 members met face-to-face four times to plan an Algebra 2 lesson on series and sequences in the spring semester of 2001. The planning meetings took place in the classrooms of the two in-service teachers so that all necessary materials were available. The face-to-face planning meetings were scheduled when most members could attend, at the end of the school day, around 3:30 pm. Each meeting took approximately one and a half hour. Between face-to-face meetings, members also communicated on-line through the Inquiry Learning Forum (ILF). The primary goal of the face-to-face and on line activities was to collaboratively plan classroom activities that would help students understand the formula for finding the sum of an infinite geometric series and be able to use it to solve problems. Although the LSG1 members brought very different experiences and knowledge to the effort, all were interested in improving mathematics teaching and learning.

### **Teaching in Mr. KB's and Ms. JP's Classes**

Mr. KB, one of the in-service teachers, taught the planned lesson in two 48-minute class periods on two consecutive days. However, Ms JP, the other in-service teacher, implemented the planned lesson in one 85-minute class period. The three classes were taught on consecutive days of the same week, in the teachers' own classrooms. When Mr. KB and Ms. JP taught, most other members of LSG1 observed the class, but did not assist the teachers during the lesson. Not all LSG members could observe both teachers' lessons because other commitments. Most importantly however, Ms. JP and Mr. KB were able to observe each other. The motivation to teach the lessons in both teachers' classes was a desire to refine the activities as much as possible and to test the viability of the plan in classes on both traditional and block schedules. The teaching was viewed as an opportunity to see if the planned instruction worked as intended.

### **Reflections on the Lesson Implementations**

The teacher who taught the lesson and the LSG1 members who observed met together immediately following each class period to reflect on the lesson and to discuss possible revisions to the plan. Much of the discussion focused on the accuracy of the mathematics and the understandings of the students. Reflection sessions took place in the teachers' classrooms and often the boards still contained work from the lesson and informed the discussions. The lesson plan was revised in ways agreed upon by the teacher and observers. LSG1 members wanted to use reflections on the experience of the taught/observed lesson to further refine their lesson plans and to better the chances of improved student learning.

### **Sharing with Other LSGs**

When all three LSGs had completed the lesson study cycle of teaching, refining, re-teaching and refining again, all the members met together to share and discuss their LSG experiences. The meeting took place in a classroom in the School of Education at the university. Participants were seated at tables in a semi circle to facilitate discussion. Ms. JP and Mr. KB shared a short video segment of one of their lessons with entire group and reflected on the clip and the lesson as planned and as actually taught. During this meeting, others asked questions and provided feedback to the members of LSG1. The primary motivation for Ms. JP and Mr. KB seemed to be that they were quite proud of the lesson and eager to share it with their colleagues.

### **Presenting at a Professional Meeting**

Mr. KB and Ms. JP decided to present the lesson developed by LSG1 at a state meeting of mathematics teachers (ICTM) that was held approximately five months after they taught the lesson. This was not an activity of all members of LSG1, but rather of the two in-service teachers alone. (We do not have data on their planning process.) The two teachers presented in a 1-hour session and one of the mathematics educators in LSG1 attended the presentation. There were approximately 50 others attending the session. The two teachers had felt very satisfied with the lesson they had taught in the lesson study cycle, particularly with the revisions made after the instruction, and had wanted to share it with other teachers in the state.

### **Characteristics of the Assistance Provided**

Our examination of the data for evidence of characteristics of good assistance activities revealed considerable information about the activities in which members of LSG1 participated and the potential for these activities to provide assistance to all of the members of the group. We paid attention to the fact that although the primary goal of the group's activities was to develop a lesson that could be used in the future by any teacher who might teach the topic, each member of LSG1 also came to the activities with another goal - to gain a deeper understanding of mathematics instruction that truly was planned with connections and communication in mind.

We now report on what we learned about the five characteristics: mutual respect and trust; intersubjectivity; responsiveness; joint projective activity; and reciprocity. Obviously again we cannot provide the depth of description that our analyses allow.

### **Mutual Respect and Trust**

All the members of LSG1 except Ms. EB had participated in the CEMI project the previous semester and thus known each other before joining the group. All participants were permitted to choose in which LSG they would work, so the member of LSG1 were there by their choice, indicating some initial level of respect and trust. In their planning process, members determined that individuals or subgroups would

complete various tasks and then the results would be brought back to the whole group. For example, in the first planning session, once a topic was decided, members agreed that they would work in groups of two or three to look for appropriate instructional tasks. Later, individuals were asked to work on the details of a particular part of the lesson plan.

At another level, there is evidence in the discourse that participants were carefully listening to each other and respecting the contributions of each member to the discussions that took place. Members would use each other's words and probe to be sure they understood the contribution a participant was attempting to make.

### Intersubjectivity

Some of the time the LSG members spent together, particularly early in the planning, was used to create intersubjectivity, developing a common understanding of the purposes and meanings of their activities as a group and beginning to develop a language to use to talk together about their lesson. In the early planning sessions, for example, each member of the group described his or her background to help other group members understand what he or she might be expected to contribute and what informed that contribution. There is evidence that group members all felt that they were working toward a commonly understood goal and that the uses of terms such as "connections", "communication", "understanding" were common to all of them.

### Responsiveness

Assistance activities are responsive to the extent they meet the learners' needs and provide assistance at the learners' level of proficiency. At a global level, the entire work of the lesson study group was a response by the group members' to their desire to learn to create lessons that are reflective of the NCTM's (2000) principles and standards. At a more individual level, we find examples of group members using another member's actions or words as a basis for some comment or suggestion. In the following example, Ms. AK and Mr. KB's assistance is responsive because it is based in Ms. JP's actions in class and their perceptions of possible problems with the mathematics.

Ms. AK: I have a question. These examples, you called them infinite series but they are finite series because you end up with an end, if you put dots after that, you might say "this is infinite series"

$$\frac{1}{4} + \left(\frac{1}{4}\right)^2 + \left(\frac{1}{4}\right)^3 + \dots + \left(\frac{1}{4}\right)^n = \frac{1}{3}$$

But we can say, "this is not actually equal to 1/3, it's getting closer to 1/3".

Mr. KB: As n approaches infinity.

Ms. JP: And that's another thing, . . . I haven't even put the infinite, I haven't tried, there's no infinity up there because we haven't used the symbol yet.

Ms. AK: And maybe  $1/4$ , the first four terms and then you say it equals  $1/3$ , maybe you could say "it approaches".

Ms. JP: It approaches

Mr. YK: Eventually it would be.

Mr. KB: You might ask "where's the missing part?"

Ms. JP: The missing part, I was wondering is it okay to say "the missing part is in that square"?

Ms AK: Yes.

### **Joint Productive Activity**

There is considerable evidence that LSG1 members felt and acted as though they were working together on an authentic task. Also there is evidence that their activities were directed toward the accomplishment of a clear, jointly constructed and recognized outcome, a good lesson and student learning. It was somewhat surprising to find the group members also had a secondary goal and that this influenced their planning and revising of the lesson. Members mentioned that they were working toward the "publication" of this lesson on the Inquiry Learning Forum website. This would involve sharing video segments, the lesson plan, student work, teacher reflections, and indicating the state and national standards the lesson addressed. This goal seemed to motivate the group members to even discuss anticipating student responses that did not occur, but might. The members seemed to be motivated by the task of creating a package of materials that would allow other teachers, who had less time to spend planning, to successfully use the lesson plan of the group.

### **Reciprocity**

Our analysis reveals that at least some participants in LSG1 were both assisted and assisting. Clearly the pre-service teachers were assisted in developing their understanding of mathematics teaching and learning by engaging in discussions with Mr. KB and Ms. JP. When sharing their lesson with the entire group of LSG participants at the end of the semester, both in-service teachers in the LSG reported that they believed they would not have attempted the lesson they taught without the assistance of their LSG activities.

On a more micro level, in the following example from a discussion, Ms. JP assists Mr. KB (and those who may use the lesson plan) by suggesting a caution. Then Mr. KB becomes the assistor when he explains his method.

Mr. KB: If there is anything you could add, a working circle, an e-mail, we can write some down, that would be great. Because you know if somebody

ends up using this, it is nice for us to provide them with anticipated questions or comments even.

Ms. JP: be careful when you go from  $\frac{1}{1-r}$  to  $\frac{r}{1-r}$ .

Mr. KB: I did the a over 1-r first.

Ms. JP: I still, I want to stop and think about where I lost my flow, that, right there, stumped them.

Mr. KB: Yeah.

Ms. JP: is that the proof you are talking about?

Mr. KB: . . . No that's a substitution, that is not a proof (Mr. KB shows on the chalkboard). I substituted r right here, and right here, . . . and then I reduced that to a over  $\frac{r}{1-r}$ .

Reciprocity allows all participants in an activity to feel valuable and also supported.

### Conclusions

The descriptions we provide here only hint at the richness of the activities in which the members of this lesson study group participated. For example, an analysis of the roles of the participants and the content of their contributions to the group will add important additional dimensions to our understanding of the lesson study activities as assistance activities. Also understanding the relationship of the lesson study activities to the culture of the schools and the university is critical. We are just beginning to unpack the wealth of information in our data and will continue the process of analyzing the activities of this and other lesson study groups in the CEMI project. Although in Japan lesson studies are primarily used in elementary schools as professional development activities, we argue that the process of a lesson study – planning, teaching, reflecting, revising, re-teaching, reflecting and revising – when engaged in seriously and over time, is a process that can assist any group of teachers to improve their instruction one or two lessons at a time.

# TEACHER LEARNING IN MATHEMATICS TEACHER STUDY GROUPS

Sandra Crespo  
Michigan State University  
crespo@msu.edu

In this paper I explore the challenges and possibilities for teacher learning in study groups by examining the typical discourse generated in one particular group. Special attention was paid to the teachers' talk when doing mathematics together and when talking about their teaching practices and students' work. When doing mathematics together, the examined group's talk can be described as exploratory talk, that is talk characterized by speakers seeking and showing intellectual involvement; public disclosure of disagreements and confusion; and talk that is generative and collaborative. In contrast, the teachers' talk about their teaching and students' work can be categorized as expository talk, which can be characterized by the use of monologues; speakers seeking and giving approval; and the non-analytical or unproblematic narration of events. These are features of study group talk that seem important to attend to and study as these affect the participants' learning opportunities and impact the design and leadership of teacher groups.

## Introduction

The notion of school-based study groups is a departure from traditional approaches to the professional development of teachers. Rather than attempting to "sell" the reform-minded ideas about mathematics teaching and learning, teacher study groups are designed as forums for critically examining and experimenting with standards-based mathematics teaching. This departure from traditional professional development activities stems from the negligible impact they have had on helping teachers realize the more ambitious goals of teaching and learning embedded in the mathematics reform documents. It has also grown out of the realization that professional development that seeks to engage teachers with "what is hard" about teaching and learning needs to happen in critical and reflective learning communities (Ball & Cohen, 1999) and that teacher learning needs to be "activated" rather than delivered (Wilson & Berne, 1999).

Recent years have seen an emerging consensus in the research literature on teacher learning about the "essential principles" of effective professional development. Putnam and Borko (2000), for example, have named the following as essential features to include in professional development opportunities for teachers: 1. Teachers should be treated as active learners who construct their own understanding. 2. Teachers should be empowered and treated as professionals. 3. Teacher education must be situated in classroom practice. 4. Teacher educators should treat teachers as they expect teachers to treat students. Wilson and Berne (1999) generated a similar list stating the typical features of successful professional development as work that: 1. Is ongoing; 2.

Is school based and embedded in teacher work; 3. Is collaborative; 4. Focuses on students' learning; 5. Recognizes teachers as professionals and adult learners; 6. Provides adequate time and follow-up support; 7. Is accessible and inclusive. It is however important to realize that "we know as little about what teachers learn in these kinds of forums as we do about what teachers learn in traditional staff development and in-service" (Wilson & Berne, 1999, p. 176). And, as Ball (1996) notes, "determining how to design provocative experiences for teacher learning and for engagement with what is hard about the reforms, while still honoring teachers as professionals, is a more complex matter than many may recognize." (p. 502).

Following on the reform-minded ideas for professional learning my colleagues and I have been working with four elementary schools that have close ties to our institution's elementary teacher preparation program. Each of us is both an instructor in the teacher preparation program and a study group leader in one of the participating schools. The idea is that by working with the teachers that mentor our students, prospective teachers will have access to teachers who are reflecting, studying, and innovating their teaching practice. The aim of our project, therefore, is twofold: (1) to strengthen our partner schools' teaching of mathematics; and (2) to strengthen the field-based component of our teacher preparation program. In this paper, however, I will focus on the insights, questions, and tentative conclusions I have drawn from my work as a study group leader in one of the teacher study groups of this project. More specifically, my aim is to address the following questions: (1) What opportunities for learning do teacher study groups afford the participants, and (2) How do different study group activities affect the nature and substance of these learning opportunities?

### **Data Sources and Analysis**

The study group I will focus on is composed of seven K-4 teachers. The group meets once every 3 weeks for 2.5 hours during school hours. Meetings began in the spring of 2001 and will continue until the spring of 2003. Six of the teachers are female, and only one of them is male. Two of the teachers have been teaching for over 20 years, two of the teachers have 7-10 years of teaching experience, and three of them are in their 2<sup>nd</sup> or 3<sup>rd</sup> year of teaching. All of the grade levels are represented in the group. During these meetings we have engaged in several professional development activities including (a) discussions of selected readings, (b) engage in mathematical problem solving ourselves, (c) analyze students' work, (d) observe and discuss someone's teaching, etc. These activities have generated multiple sets of data, which have been recorded and collected. Teacher educators' project and planning meetings, for instance, have been audio taped. The teacher study group sessions have also been recorded, with both audio and videotapes. Teachers have been observed and video taped teaching in their classrooms. Written data from the students, from the teachers' notebooks, and the teacher educators' journals are also available for analysis.

One of the main foci of our teacher study groups is to engage teachers in the exploration of mathematics through problems that challenge and extend their own understanding. There are obvious reasons for focusing teachers' professional development on doing mathematics. Teachers need to understand the subject matter they teach (Ball & Cohen, 1999; Ma, 1999). Otherwise, they are confined to a practice of showing and telling that does not allow students to figure things out on their own. The analysis of students' mathematical work is also another important focus of our teacher study groups. Understanding what students say, do, and write is an important aspect of teaching that values, respects, and encourages students' thinking. We draw from the professional development ideas and materials of CGI (Fennema et al, 1996) and DMI (Schifter et al., 1999a, b) to structure the study groups' discussions about students' thinking. We also structure conversations around the participants' own students' work on problems the teachers have first worked and discussed in their respective study groups and then tried out with their students.

In this paper I will focus the analysis on the kinds of conversation that take place in a typical study group meeting. In a typical meeting, the study group leader poses a rich mathematical problem to the teachers. These problems are chosen with many of the NCTM's (1991) criteria for worthwhile tasks, such as problems that generate opportunities for mathematical discussion and exploration of mathematical ideas. In addition, the study group math problems are chosen or constructed so that they are accessible for different levels of mathematical sophistication and that are adaptable to different elementary grade levels (K-5). The structure of a typical study group meeting is akin to Simon's (1994) "learning cycles" for mathematics teacher education. In our case, the study groups have four learning cycles—Solving, Posing, Interpreting, and Reflecting. The solving and posing phases occur when the teachers solve a particular mathematics problem together and discuss and analyze their solutions and ways of posing the problem to their students. The interpreting and reflecting phases, in turn, occur after the teachers have tried their version of the problem in their own classrooms and come to the study group meeting prepared to share classroom stories along with insights into their students' thinking and their teaching practice.

A major assumption driving the analysis of the data is that opportunities for teacher learning and change in a community of learners, such as in teacher study groups, depend a great deal on the participants' willingness to share their ideas and to examine their own and their peers' ideas critically. Hence, particular attention is paid to participants' disagreements and challenges of each other's ideas, as well as to the participants' talk that reveal uncertainty, surprise, and confusion. These elements have long been considered instrumental to the personal construction of knowledge and to a community's generation of knowledge. This kind of professional talk, however, is not without some serious challenges. Chazan and Ball (1999), for example, have suggested that most discussions about teaching in all circles tend to be too judgmental to

support analytical and constructive conversations about practice. Similarly, Pfeiffer and Featherstone (1995) have noted: "when teachers talk about their work, most are quite facile in talking about teaching without revealing the struggles and uncertainties inherent to the practice." Lord (1994) also contends that in order for teacher groups to become a setting for teacher learning, teachers must be prepared to openly and publicly disagree with and about practice and to engage in a "critical colleagueship" which he defines as "an alternative professional stance where teachers move beyond sharing and supporting one another through the change process to confronting practice—the teachers' own and that of his or her colleagues."

In order to make sense of this data I have drawn from the situated learning perspectives, such as Wenger's (1998) "communities of practice," and the emergent "situative perspective" in cognitive science (Putnam & Borko, 2000), which also emphasizes the social nature of cognition. In addition, because the nature of learning in study groups is discourse-based, several discourse analysis frames such as, "turn-taking", "participant's involvement," "politeness," "disagreements" and "concensus" (Cazden, 1988; Tannen, 1989; 1993) are used to uncover conversational patterns and explore Lord's notion of "critical colleagueship" or whether and when do teachers openly and publicly disagree with one another.

### Results

A survey of the participants' assessment of the study group meetings revealed that at least in the teachers' minds, teacher study groups provide them with multiple opportunities for professional learning. Teachers have reported learning and enjoying the experience. The main attraction and learning opportunity, they have said, comes from being able to work across grade levels, which they say has given them opportunities to learn about curricular issues, students' understandings, and teaching struggles at the different grade levels. They have also reported that working on mathematics problems together and then trying them with their students to later report back to the group on what happened and what they learned from the experience has not only further their own understanding, but also has affected their teaching practices. When asked how the study group work were helping them, teachers for example wrote:

I've really enjoyed the opportunity to get together and talk/share with other teachers about mathematics. I've seen myself look more critically at how I talk or ask questions to the class during a math lesson. I also have seen myself grow in the area of challenging my students... not being afraid to give them an open-ended story problem (*Special Education Teacher*).

I find myself pushing my students to think beyond more. Instead of stopping at solving a problem one way, we talk about alternatives. We also do more thinking/talking about connections to other problems (*Second Grade Teacher*).

### Features of Study Group Talk

A closer look at the discourse generated in the study groups have revealed important differences in the pattern of the group's talk when teachers are engaged in the doing of mathematics and when they talk about their own teaching and students' work. Each of these activities generates distinct conversational patterns of talk and involvement by the participants. These unique forms of talk and participation provide both challenges and possibilities for teacher learning. When doing mathematics, for instance, the teacher group's talk in this study tends to be very interactive and collaborative with participants interrupting and disagreeing with one another, freely and unprompted. Yet, when the focus of the conversation shifts towards their practice and students' work, the conversation tends to take on a different character. This talk is less interactive and collaborative, as one speaker would speak at a time uninterrupted and in a monologue style. These findings are elaborated next.

In terms of the structural features of the teachers' discourse around their own doing of mathematics, it is interesting to note the very public and explicit disagreements that are uttered. The speakers, for instance, explicitly object to another person's solution using "but," "no," and "I don't think so." In addition, the teachers' talk seems more like exploratory talk rather than a polished exposition of ideas. That is to say that the group seems to be figuring things out together and extending perhaps even revising their ideas as they talk. The focus of such conversations is on the analysis of everyone's solutions rather than on simply reaching or agreeing on the right answer. Furthermore, teachers use phrases that indicate uncertainty and exploration of ideas such as "what if," "maybe," "what about" and "I'm not sure."

The group's involvement is another prominent characteristic of this talk. The number of speaking turns and the multiple speakers on the same topic are some evidence of this. In addition, there are several instances in the transcripts where the speaker and listeners show involvement (Tannen, 1989). There are multiple instances of speakers using phrases that suggest they were seeking or showing involvement and understanding such as: "does that make sense?," "you know what I mean?," "what did you say?," "okay I see what you're saying." Another example of involvement is when the participants finish each other's sentences. In addition multiple instances of "repetition" were uncovered in the transcripts, which is another indicator of involvement. Repetition is a conversational strategy used by speakers in order to check for understanding or better understand what has been said.

In contrast, when the conversation is focused on the teachers' teaching practice and students' work, the structure of the conversation changes. The turn taking pattern is different. When sharing their practice, each teacher takes uninterrupted turns and presents with varying levels of detail and analysis what they had done and what their students thought and did in relation to the math problem everyone has tried. Also, interesting is the fact that no one except for the group leader actually asks questions to

the speaker. It is also important to note that the teachers in the focus study group have shown a genuine excitement and interest in their students' work regardless of whether the work is correct or incorrect. Their talk therefore tends to be non-evaluative and somewhat celebratory of the students' work, but it also tends to be more descriptive rather than analytical of the mathematical work. Another interesting feature of the conversation is a lack of explicit disagreements; there are no "but" or "no" spoken, even when differences of opinion are expressed. Very explicitly spoken, however, are phrases that imply certainty such as: "probably," "definitely," and "must have." Teachers also use repetition of certain key phrases such as "I think," "in my opinion," and "my students." For instance, when a teacher was asked what might happen in her classroom, she responded by referencing the fact that she had taught both first and second graders before she stated her response. With such conclusive statements that make reference to their expertise, number of years teaching, or their opinion, teachers seem to position themselves as the ultimate authority on what they think and on their students. It is therefore hard to imagine anyone disagreeing or arguing with anything that anyone says.

Another interesting aspect of the teachers' talk about their practice and students' work is the amount of details that the teachers are able to recall and report. Some teachers, for instance, have been able to report the chronology of students' contributions or reproduce what the students say with great accuracy. Still others use "reconstructed dialogue" (Tannen, 1989) in their narrations. The reconstructed dialogues may or may not represent actual dialogue but serve to involve and engage the audience in one's story. It is therefore interesting and puzzling that although some elements for potentially collaborative conversations are present, the teachers' talk about their practice have tended to be anything but collaborative. This is surprising because as Tannen suggests "details create images, images create scenes, and scenes spark emotions, making possible both understanding and involvement" (p. 135). However, Tannen also suggests that a speaker or writer may use details and images to lead hearers and readers to draw the conclusion favored by the speaker or writer. She also cautions that, "one can fabricate details to make a false story sound true, or pile on details about irrelevant topics to de-fuse, diffuse, or avoid a relevant topic" (p. 161). In these teachers' case, then, the provision of detail and images can be thought of as a strategy to involve the listeners in order to help them draw the same conclusions the speaker reached and not necessarily as a way to engage listeners in further analysis of the described experience.

### **Opportunities for Learning**

The two kinds of group talk I have discussed also provide multiple learning opportunities to the participants. When doing mathematics together, the participants have opportunities to: explain their thinking, make sense of someone else's explanation, offer counter-explanations of problems, and participate with others in discus-

sions about the meaning of problems or mathematical ideas. During the sharing of their students' work, in turn, the participants have opportunities to: make observations about children's work and ideas; contrast what children said and did with what participants anticipated they would do or say; consider differences between children's and adults' perceptions of the problem; develop conjectures about alternate approaches to presenting problems or about follow-up activities or problems. These are aspects of professional learning that are considered to be important to the teaching of mathematics as discussed by the National Council of Teachers of Mathematics (2000; 1991); the National Research Council (2000); and the Conference Board of the Mathematical Sciences (2001).

These opportunities for learning depend a great deal on the selection of tasks used in the study groups as they allow different kinds of content and processes to be explored and yield different possible mathematical learning outcomes. In all of the examined transcripts, the problems used have engaged the teachers in explaining and clarifying their own mathematical thinking, and in listening to others' explanations and ways of solving. Participating in these two activities have afforded teachers the opportunity to expand their repertoire of possible solutions or approaches to particular problems. This can be inferred from the analysis of the group's discourse when teachers use expressions of surprise after hearing somebody else's solution, indicating that a particular approach or solution is new to them. Another indicator or source of evidence can be found when teachers are compelled to repeat somebody else's solution word by word, which is a conversational strategy many use in order to better understand what has been said. One other example that supports the notion that conversations around their own doing of mathematics can serve to expand teachers' repertoire of solutions to problems can be seen when teachers disagree with another's solution and try to convince each other that their solutions is or is not mathematically sound.

When discussing ways of posing the same problem to their K-4 students and what might happen in their classrooms, the teachers' conversations have revealed multiple opportunities for professional learning. The teachers' attempts to anticipate what their students might think and how they would "nudge" them towards seeing other solutions beyond their own often led to further analysis of the problem and how it is different from the "typical" math problems they would pose in their classrooms or previous problems the group had tried. In one such conversation, for instance, the first grade teacher said that "unless I really read this over" pointing to the last sentence in the problem, her students would automatically want to prove one of the two kids in the problem right, because that is what math problems tend to ask them to do. This led to a discussion about: "do you want it to even say that (prove that both kids could be right) or would you want it have it say "which one is right?" This suggests that engaging teachers in discussions about how they might pose problems to students can provide opportunities to analyze math problems from different vantage points—the wording, structure, demands, challenging aspects, etc. across the different grade levels.

In terms of opportunities for learning when sharing and listening to each other's accounts, teachers have multiple opportunities to extend their pedagogical content knowledge, and their knowledge of students' mathematical thinking. By listening to others' accounts, the listening teachers have opportunities to learn about the speaking teachers' practice. This opportunity depends a great deal on how much of their practice the reporting teacher is willing or able to reveal. From listening to others' accounts, participants can learn that the reporting teacher, for example, had "read the problem" to her students, or that she decided against bringing actual manipulatives because she "didn't want to have predetermined solutions for them." Teachers' report on what happened in their classroom also provided opportunities for learning about the different solutions and ways of thinking from students in classes that were different from their own and how the reporting teacher had made sense of them. It is, however, unclear and harder to determine how the reporting of their insights, in turn, helped extend or challenge anything that the reporting teachers may have already learned. The opportunity for extended learning in this situation, therefore, depends a great deal on the reporter's willingness to publicly problematize their teaching practice and their students' work. It also depends a great deal on the availability of records of practice for everyone to examine and also on the study group leader's mediation and interjections.

One of such interjections that have proven very fruitful often happens when the group leader moves the conversation from a reporting to a reflective mode by asking the participants, for example, to talk about "what was hard about doing this problem with students?" In this reflection mode the participants would often reveal more about their pedagogical thinking and the problematic aspects of their teaching that were not revealed when they reported on their teaching and their students' work. One teacher, for instance, who in the reporting/analysis phase sounded self-assured and her practice sounded straightforward, revealed the tensions she experienced when deciding when it was time to move on.

I struggled with the chunk of time that you talked about too. We had 6 different pictures and solutions all over the board and when I finally cut it off I still had 4 or 5 kids with their hands up wanting to say something more and come up to the board. I mean I wanted to get some other things done in math and we had already spent I think 25 minutes on it. You know between the pre-discussion and giving them the problem and having them start talking about it, and giving them some paper to draw on and then all the different answers and getting them to the board, it was really hard. Although I don't think I would have gotten some of the interesting thoughts in the end if I didn't give them extra time to process but it was hard to give up the time and keep going and still wonder if I should have continued on going. (Second Grade Teacher)

To summarize, in the *solving* cycle teachers have opportunities to engage in the doing of mathematics. This work affords them opportunities to (a) explore and discuss their own mathematical solutions and approaches to proving or refuting (b) identify and expand their knowledge and beliefs about particular mathematical content and approaches to learning it, and (c) evaluate the problem's potential for supporting students' learning. The *posing* cycle provides teachers the opportunity to: (a) explore the contextual, mathematical, and linguistic demands of the problems, (b) anticipate and prepare for students' difficulties, and (c) design versions of the same problem to try out with students in different grade levels. In the *interpreting* cycle teachers: (a) explore students' mathematical work across grade levels, (b) identify insights they have gained about teaching and about students' mathematical work and understanding, and (c) develop analytical frames to interpret teaching and students' learning. The *reflecting* cycle, in turn, provided teachers the opportunity to (a) explore what they and their students might have learned, (b) identify effective practices and aspects of their current practice that they may wish to examine further or change, and (c) map possible plan for follow up and investigation into their teaching and students' learning.

### Insights, Questions, and Issues

An important insight from this study is the differences between the two types of talk explored in this study and the learning that each can afford. Teachers' problem solving discourse can be categorized as exploratory talk, that is talk that is characterized by speakers seeking and showing intellectual involvement; explicit disagreements and public disclosure of uncertainties and confusion; and talk that is generative, interactive, and collaborative. In contrast, the teachers' talk about their teaching and students' work can be categorized as expository talk, which can be characterized by the use of monologues; speakers seeking and giving approval; and non-analytical or unproblematic narration of events. These are features of study group talk that seem important to pay attention to and study. Another important insight relates to the opportunities for learning that these two forms of talk afford the participants. When the conversation is focused on their own mathematical problem solving and the structure of the talk is exploratory the participants have opportunities to explore and analyze mathematical ideas and expand their repertoire of solutions and approaches to particular problems. When the discussion focuses on their teaching practice or students' work and the talk is expository, the participants have opportunities to expand their repertoire of students' solutions and strategies and to glance at each other's teaching moves and pedagogical reasoning.

After this analysis it has become clear that engaging teachers in discussions about their own mathematical ideas is likely to provoke a more generative and collaborative talk than conversations that focus on teachers' practice or their students' work. The more collaborative form of teacher talk happened more "naturally" and without much intervention from the study group leader when participants engaged in, and discussed

their own, problem solving activity. This has turned out to be somewhat surprising. I, for one, would have thought that talking about mathematics would be more intimidating to elementary school teachers who are known to have a weak mathematical background and sometimes negative dispositions towards the subject. There are, however, different plausible explanations of what I have described. It is possible that for elementary school teachers admitting mathematical ignorance is not as threatening as admitting dissatisfaction or problems with one's teaching (whereas the contrary might be true for secondary school teachers). They may not find it threatening to their professional status or self-worth. Paulos (1988) has noted that the great majority of Americans openly say they are not a "math person" or were "never good at math."

Another plausible reason is that teachers are more likely to have been engaged in mathematical discourse than they would be used to talking about their teaching practice with colleagues. It is therefore a resource that they bring with them to the teacher study groups. Yet another explanation is the power of a "shared experience" in promoting and sustaining collaborative discussions. Having just solved a problem and talking about it is much easier to handle as a participant and as a facilitator than a conversation that focuses on each participant's individualized experience from a few days ago. The point here is that for the uninitiated participant (and leader) of study groups, doing problem solving seems to be a fruitful setting to begin to engage in the kinds of discussions that might lead to the "critical colleagueship" orientation Lord advocates, and to the adoption of patterns of discourse that are more analytical rather than simply descriptive or evaluative of one's and others' teaching and students' work.

By the same token, the analysis of the conversations centered in and around practice and students' work seemed to be less amenable and open to collaborative talk. The form of the teachers' talk I have called "expository" tended to keep participants away from becoming involved and from asking questions or challenging the speakers' interpretations. The lengthy and intricate stories the participants told while vivid and memorable in many respects were not conducive to interactive and analytical discussion. The study group leader's interventions then are the most crucial in this setting. Modeling the kinds of questions that would further the group's collective insight, asking participants to comment on each others' accounts, and asking participants to comment on analytical questions such as what sense or insights they gain from listening to each other or what they found hard or problematic were some of the interventions that seemed to generate more revealing and collaborative discussion. It is however important to point out that teachers' expository talk also provided multiple opportunities for learning to the participants. Absent from that kind of talk, however, were opportunities for the teacher reporter to hear others' perspectives, challenges, and questions about their interpretations and narrations of their classrooms and students' work.

## TEACHERS RESPOND TO MATHEMATICS REFORM PROFESSIONAL DEVELOPMENT

Julie Cwikla  
University of Southern Mississippi  
julie\_cwikla@yahoo.com

Do particular professional development activities supporting teachers' implementation of new mathematics curricula encourage their attendance to reform-minded features of classroom practice? In particular, this study investigated middle school mathematics teachers' reports of the effectiveness of various professional development activities influencing their attention to students' thinking. Teachers' entry characteristics, nature of the activities themselves, and teachers' ratings of the activities were the focus of this study. Teachers were surveyed ( $n = 110$ ) to rate each activity's effectiveness in prompting their attention to students' thinking. Teachers' years of experience, views of learning, and mathematics background correlated with their ratings of various activities. Teachers ( $n = 13$ ) were interviewed to extend the quantitative results and illuminate the reasons individual teachers rated particular activities as very effective to not effective at all.

The National Council of Teachers of Mathematics (NCTM) developed a set of Standards for K-12 mathematics curriculum, teaching, and assessment. The Standards build on (a) a consensus emerging in the empirical evidence in the literature describing effective practice and (b) the learning goals most valued by the mathematics education community (Hiebert, 1999). Accompanying the release of the Standards has been a surge of new mathematics curricula designed to align to the NCTM Standards. When teachers are working with materials aligned with the NCTM Standards, it is reasonable to suspect that teachers might become more attentive to the ideas central to the mathematical reform agenda by using and learning about the curriculum.

One of the NCTM Standards (2000) claims that "effective mathematics teaching requires understanding what students know and need to learn, and then challenging and supporting them to learn it well" (p.16). To follow the above NCTM recommendation it is necessary for teachers to investigate their students' mathematical thinking and learning. It has been documented that when professional development activities focus on students' thinking, they can have a positive effect on teachers' instructional practices and provide support for teachers' continued growth (Franke, Fennema, Carpenter, Ansell, & Behrend, 1998; Simon & Schifter, 1991). Therefore, might teachers become more aware of students' thinking by using and studying these NSF curricula? In this study, I investigate two factors: (a) the nature of the professional activities themselves and (b) the entry characteristics of the teachers. The key is to find a way of classifying professional development activities and teacher characteristics that might relate to changes in teachers' attention to students' thinking. The literature provides some useful direction.

## Background

### Nature of Professional Development Activities

One way to summarize the diverse literature on professional development is to tease out the factors found throughout the literature that seem to characterize effective development programs. Although confirming empirical data are sketchy, many researchers are hypothesizing that effective professional development is based on various principles or frameworks of design (e.g., AFT, 1995; Guskey, 1997; Hawley & Valli, 1999; Lampert & Ball, 1999; Sparks & Loucks-Horsley, 1989; Sykes, 1996). There is an emerging and rather striking consensus regarding the core mechanisms of effective professional development. These mechanisms are viewed best as *hypotheses* (described below) that should be investigated empirically. The four mechanisms were chosen because of their empirical support in the literature. Aside from several detailed research studies, such as the Cognitively Guided Instruction (CGI) (e.g., Fennema, Carpenter, Franke, Levi, Jacobs, & Empson, 1996) and Summer Math programs (Schifter & Fosnot, 1993; Simon & Schifter, 1991), relatively little data have been reported that address these hypotheses directly in mathematics so it is difficult to know exactly how these emerging mechanisms facilitate teachers' learning and changes in practice.

*Professional Mechanism 1: Instructional improvement is facilitated when teachers' thinking and learning is focused on students' thinking and learning (M1).* Empirical evidence suggests that professional development activities should be grounded in the fundamentals of student cognition (Carpenter, Fennema, Peterson, Chiang, & Loef, 1989; Fennema, et al., 1996; Schifter & Fosnot, 1993). Students' thinking and learning are the products of teaching, and teachers might benefit if these products are a driving mechanism of their professional activities.

*Professional Mechanism 2: Instructional improvement is facilitated by teacher collaboration (M2).* Little (1982) collected interview and observation data from six schools and posited that professional development has the greatest influence when it occurs in a collegial environment where teachers believe they can learn from one another. A collaborative teacher culture that encourages consistent improvement and supports teacher development might be beneficial for reform (Ball & Cohen, 1999; Schifter & Fosnot, 1993).

*Professional Mechanism 3: Instructional improvement is facilitated by small steady change (M3).* Research studies suggest that the focus of improvement should be small and intense for thorough progress in instruction (Franke, Carpenter, Levi, & Fennema, 2001; Schifter & Fosnot, 1993). Gallimore (1996) describes classrooms as cultural routines. One facet of the routine cannot be changed without influencing other cultural routines, shaking the classroom equilibrium creating discomfort and confusion. Changes in the learning environment might last longer and be more effective when teachers focus on small changes over time.

*Professional Mechanism 4: Instructional improvement is facilitated by teachers' experimentation and inquiry (M4).* Encouraging teachers to share and conduct structured learning experiments in their classroom instruction might support teacher learning (Schifter & Fosnot, 1993). Few teachers are given the opportunity to observe one another but watching and learning from peers might be a useful mechanism for professional development (Little, 1999). In addition to a collaborative environment, Little's (1982) study also indicated that schools that supported a norm of "analysis, evaluation, and experimentation" were relatively more successful (p. 339).

These mechanisms are not discrete entities or requirements on a checklist but are overlapping recommendations from the literature that might foster continuous teacher development and growth. These Professional Mechanisms were used to classify various professional development activities for analyses.

### **Teachers' Entry Characteristics**

This study investigated characteristics that might be associated with teachers' attention to student thinking. Three themes emerged from the literature to guide hypothesis development: teaching experience, views of learning, and mathematics background.

#### **Teaching Experience**

Huberman (1995) presents a summary of the literature and a model to generate hypotheses about how years of teaching experience are associated with teacher responses to professional development. Two of the five phases are described in ways that suggest links between a teacher's career phase and the nature of particular development activities. This study investigated two phases. A teaching career typically begins with two years in a "survival and discovery" phase. Teachers are confronted with the initial complexity of teaching, yet are generally enthusiastic, experience a sharp learning curve, and develop pride in belonging to the teaching profession (Huberman, 1995). The less experienced teachers have not been socialized into the typically individualistic and isolated teaching environment, which lacks meaningful interaction (Ball & Cohen, 1999; Lieberman, 1988; Little, 1999).

H1: Teachers with less than two years of experience perceive professional development activities involving Professional Mechanism 2 (Collaboration) as a productive way to prompt their attention to students' mathematical thinking. They will rate these activities higher than 2.5 on a 1-4 Likert-type effectiveness scale.

Later in the teacher's career, Huberman (1995) identified an "experimentation and diversification" phase that might emerge between seven and twelve years of experience. Teachers have come through the "survival and discovery" phase as well as a "stabilization" period and begin exploration in their teaching. This phase is charac-

terized by a desire to increase teaching effectiveness and is enacted through “largely private experiments” in their own classroom (Huberman, 1995; p. 198).

H2: Teachers with seven to twelve years of experience will rate activities involving Professional Mechanism 4 (Experimentation) higher than teachers with either less or more years of teaching experience.

### **View of Learning**

A second lens through which to examine teachers’ interactions with professional development is their view of student learning. Knapp and Peterson’s (1995) findings suggest that teachers who view mathematics learning as knowledge construction are likely to give attention to student thinking, whereas teachers who maintain that knowledge is transmitted give little credence to the diversity of student thinking in their classroom.

H3: Teachers who hold a student-centered view of mathematics teaching will rate all the professional development activities higher than teachers with a curriculum-centered view of teaching in terms of prompting their attention to student thinking.

### **Mathematics Background**

Middle school teachers might vary greatly in their mathematics education. In general, middle school teachers range from mathematics and mathematics education majors to uncertified teachers. Teachers’ mathematical background might influence the manner in which they structure their classroom (Brophy, 1991; Fennema & Franke, 1992) and impact their attention to student thinking. It is suspected that the advanced mathematical teachers might not feel they are challenged and the teachers with a weak background might be confused or feel lost.

H4: Teachers with an average number of college mathematics credits within the group will rate the sessions focused on student strategies or development of the content, higher than the teachers with more or less mathematics credits. These teachers might be most interested in activities that embody Professional Mechanism 1 because their mathematics foundation allows these activities to be accessible but still leaves room for learning.

There might be other explanations for the differences in teachers’ responses to various types of professional development activities, but this study focused only on these three specific teacher characteristics.

## **Method**

### **Participants**

The participants were a voluntary sample of 110 teachers from a population of approximately 200 middle school teachers in a mid-Atlantic state in the U.S. All of

these teachers were participating in a statewide mathematics professional development program with a two-week summer program for first year teachers and a one-week program for second and third year teachers. All teachers also participated in on-site professional development activities throughout the school year that blend all teachers. Most public schools in the state had chosen to use one of two reform driven curricula at the middle school level. Teachers in these schools were required to attend the professional development activities. This mandate increased the likelihood of a well-stratified sample of teachers from across the state, not limited to the usual set of volunteers and self-motivated teachers.

## **Data Collection**

### **Survey Constructs**

The teachers filled out a written survey after they had experienced a variety of professional development activities halfway through an academic year. The survey included items that investigated teachers' reactions to the various forms of professional development and activities that prompted teachers' attention to student thinking. The survey consisted of three sections. (a) The first measured teachers' views of mathematics teaching. (b) The second explored teachers' reactions to specific forms of professional development in prompting their attention to students' mathematical thinking. (c) The third portion collected demographic information. Prior to survey administration, I coded each of the activities by the four Professional Mechanisms. Inter-rater reliability was achieved with 100% agreement on the mechanism classification of each activity.

### **Follow-up Investigation**

Each of the hypotheses guided the analyses of the survey data. To gain insight into the reasons for teachers' survey responses and why the hypotheses were confirmed or not confirmed the investigation shifted to focus on individual teachers. Eighteen teachers were contacted by telephone to verify their survey responses regarding demographic information and professional development ratings. An attempt was made to select teachers that were stratified along the other variables in this study to obtain a diverse sample.

### **Teacher Interviews**

Thirteen teachers were interviewed in-person after one teacher declined an interview, two did not return multiple phone calls, and two others were rejected because the researcher judged the teachers not to be a productive source of information by their answers in the phone follow-up. The thirteen interviews were recorded and transcribed. For each hypothesis three teachers were interviewed except for the third hypothesis that investigated teachers' views about learning, and four teachers were interviewed. Of the four, two teachers were chosen from each of the extreme ends

based on their survey responses. In-depth interviews were conducted to inform the affirmation or refutation of each of the primary hypotheses. The in-person interview addressed the survey questions and asked teachers for specific examples and details about their professional development experiences and how the activities impacted their understanding of students' thinking.

### Results

The results section reports the hypotheses testing using the survey data. The qualitative data collected during the teacher interviews will be reviewed in the discussion section to inform the results of the hypothesis tests. The goal is to provide both a quantitative and qualitative description of teachers' reports about their attentiveness to students' thinking and the professional development activities that influence that attention.

An alpha level of .05 was used to determine significance for all statistical tests. Hypothesis 1 was tested using the professional development ratings of the 20 teachers in the sample with less than two years of teaching experience. The teachers in Huberman's (1995) "survival and discovery" phase rated all four activities that incorporated Professional Mechanism 2 (Collaboration) higher than 2.5 on a 1-4 Likert-type scale (See Table 1). A t-test confirmed that all of the means are significantly greater than 2.5, rejecting the null hypothesis.

Hypothesis 2 was tested using a multivariate analysis of variance (MANOVA). There were four dependent variables, activities 3, 4, 6, and 9; and three levels associated with teachers' years of experience, 0-6 years, 7-12 years, and more than 12 years. Although the means were in the direction hypothesized, no significant differences were indicated by Wilk's criterion across the teachers' years of experience and their ratings of activities exhibiting M4 ( $\Lambda = .662$ ). A power analysis indicated a relatively low level of power (Power = .32), possibly the result of the small sample in the 7-12 years of experience group. The MANOVA, which analyzes only the cases that rated all four activities, did not produce results significant to reject the null hypothesis. The descriptive statistics for each of the teacher groups are detailed in Table 2.

**Table 1.** Teachers' Ratings With Less Than Two Years of Experience

|            |      | SD  | t-test |
|------------|------|-----|--------|
| Activity 2 | 3.13 | .83 | 15.19  |
| Activity 3 | 3.23 | .75 | 19.54  |
| Activity 7 | 3.09 | .94 | 13.14  |
| Activity 8 | 3.05 | .70 | 16.46  |

**Table 2.** Teachers and their Mean Ratings & SD of M4 Activities

| Experience | N  | Activity 3    | Activity 4    | Activity 6    | Activity 9    |
|------------|----|---------------|---------------|---------------|---------------|
| 0-6 Years  | 44 | 3.20<br>(.73) | 2.90<br>(.78) | 2.75<br>(.71) | 3.06<br>(.81) |
| 7-12 Years | 17 | 3.29<br>(.62) | 3.20<br>(.86) | 3.16<br>(.98) | 3.30<br>(.67) |
| 12+ Years  | 34 | 3.03<br>(.82) | 2.91<br>(.83) | 2.80<br>(.95) | 2.60<br>(.83) |

Hypothesis 3 was also evaluated using a MANOVA. The 110 teachers' views of teaching spread across a continuum. To form two distinct groups, twenty teachers were chosen who held views that were most different. Wilk's criterion confirmed that teachers who hold a view of teaching as best when student centered rate *all* professional activities higher with regard to prompting their attention to students' thinking ( $\Lambda = .007$ , Power = .884). Descriptive statistics are summarized in Table 3.

**Table 3.** Teachers' Views of Teaching, their Average Ratings, and SD

|                     | N  | M1            | M2            | M3            | M4            |
|---------------------|----|---------------|---------------|---------------|---------------|
| More Constructivist | 20 | 3.33<br>(.51) | 2.95<br>(.66) | 3.20<br>(.57) | 3.40<br>(.49) |
| Less Constructivist | 20 | 2.75<br>(.48) | 2.49<br>(.38) | 2.59<br>(.45) | 2.76<br>(.41) |

The univariate results also provided significant results indicating that the "student-centered" teachers rated each of the professional activities higher than the "curriculum-centered" teachers did (See Table 4).

**Table 4.** Univariate Results for each Professional Principle

| Dependent | F      | Significance |
|-----------|--------|--------------|
| M1        | 11.545 | .002         |
| M2        | 6.846  | .013         |
| M3        | 12.252 | .001         |

Hypothesis 4 was investigated using a MANOVA. The Wilk's criterion ( $\Lambda = .041$ , Power = .821) indicated significant results for the interaction between teachers' number of university level mathematics courses and their ratings of activities exhibiting M1. The average number of mathematics courses for the entire sample of middle school teachers surveyed was 6.98 and teachers were included in the "average" group if they were within  $\frac{1}{2}$  a standard deviation on either side of the mean. Examining the univariate statistics shows significant differences for two of the four activities (See table 5).

**Table 5.** Univariate Results for each M1 Activity

| Dependent   | F     | Significance | Power |
|-------------|-------|--------------|-------|
| Activity 3  | 3.655 | .032         |       |
| Activity 5  | .8310 | .418         | .19   |
| Activity 6  | 3.618 | .034         |       |
| Activity 11 | .147  | .864         | .07   |

Significant differences across teacher groups for Activities 3 and 6 were detected. But the power of this test was especially low for activities 5 and 11 and might account for the lack of significant differences in these cases. However, the means for activity 11 show very little between-group difference. Many of the teachers reported that they could not remember how many mathematics courses they had taken and left the item blank on the survey. The descriptive statistics are reported in Table 6.

### Discussion

The discussion section reviews the results of the hypothesis tests and augments the findings with excerpts from the teacher interviews. The goal of the teacher inter-

**Table 6.** Teachers and their Mean Ratings & SD of M1 Activities

| No. Mathematics Courses | N  | Act. 3        | Act. 5        | Act. 6        | Act. 11       |
|-------------------------|----|---------------|---------------|---------------|---------------|
| Low                     | 15 | 3.29<br>(.71) | 2.57<br>(.88) | 3.09<br>(.90) | 2.91<br>(.79) |
| Average                 | 31 | 3.30<br>(.74) | 2.80<br>(.95) | 3.14<br>(.91) | 2.92<br>(.76) |
| High                    | 11 | 2.75<br>(.77) | 2.66<br>(.84) | 2.38<br>(.65) | 2.88<br>(.78) |

views was to inform teachers' ratings of professional activities on the survey. When the teachers were interviewed regardless of the hypothesis being investigated, the teachers did not keep their responses focused only on students' thinking. It seemed teachers were rating the activities on a range of goals they had in mind instead of restricting themselves to only prompting their attention to students' thinking.

### **Hypothesis 1**

Teachers with less than two years of experience rated all collaborative activities (M2) as "effective" or "very effective" in impacting their attention to students' thinking. However, during the interviews the teachers conveyed both positive and negative collaborative experiences. The inexperienced teachers reported that collaboration with their peers working through mathematical tasks together was helpful in understanding students' thinking. This is illustrated in the following excerpt from Mark a first year teacher.

When you see how other peers' minds are thinking. You know, 'Oh, I didn't think about that one.' . . . And they can actually explain it to you. . . because they are math teachers also. . . As opposed to, if you were to hear a student form a question for the first time. . . Whereas a peer teacher was able to explain the whole thinking process. (Mark, March 2001; p.3)

This collaborative activity and others the teachers discussed were part of the formal training provided through the local systemic change initiative in district wide or Statewide programs. The teachers had not experienced such positive interactions in their school on a daily, weekly, or monthly basis in general. Eileen expressed a frustration with the peers in her building during their after school meetings to discuss the reform curriculum. "I don't know if they just think that I'm too optimistic. I'm not sure. Because, when we do have meetings like I said, they're so negative. And it's frustrating to me, because I'm so positive about everything. I know the kids can do it. I've seen them do it" (Eileen, March 2001; p. 9). The interviews suggest that the three inexperienced teachers had experienced effective forms of collaboration with their wider peer group, but each also recalled negative instances of building level interactions. Despite varied levels of effectiveness reported during their interviews, they retained the view that collaboration could be an important mechanism for their own learning about students' thinking.

### **Hypothesis 2**

The statistical results from the test of Hypothesis 2 were inconclusive. There were no significant differences between the groups with different years of experience on their ratings of activities that involved experimentation and inquiry. However, the average ratings for the groups of teachers were in the direction of the hypothesis and three teachers in the "experimentation and diversification" phase with 7-12 years of

experience were interviewed. The interviews provide some specific details about what these teachers found beneficial to enhance their understanding of students' mathematical thinking, within the professional activities involving experimentation (M4).

Maria, a teacher with seven years experience reported the benefits of journal reading to improve her instruction and student learning. "Just finding other strategies, sample problems, the way that teachers kind of change and tweak different parts of the books, and curriculum they're using. Just hearing about other things, how other teachers are doing, as well as giving me ideas of how I can change my teaching to be more effective for the kids" (Maria, April 2001; p.6). Leslie, another "experimentation" teacher described a teacher support group that has been established at her school. This group meets weekly after school to explore the curriculum, the difficulties teachers are encountering, and has some similar underpinnings to Japanese lesson study. "The support here at the school that we've established, . . . being able to also use somebody else as a sounding board. 'Here's a lesson I'm really struggling with. Here's a concept I'm really struggling with, can you help me? Here's something my kids are really struggling with. Any ideas? Any suggestions?'" (Leslie, April 2001; p.14).

An understanding of students' thinking is embedded in the conversations Leslie experiences in her school.

The three experimentation teachers interviewed conveyed a sense of confidence in their teaching. They were also explicit about the methods they use to improve their practice. The professional development experiences they reported as beneficial range from observers in their classroom and journal reading, to lesson study type activities and watching classroom videos, yet their comments were not solely focused on understanding students' thinking.

### Hypothesis 3

Teachers with a student-centered view of teaching rated *all* the professional development activities more effective in impacting their understanding of students' mathematical thinking compared to teachers with a curriculum-centered view of teaching. Joanne classified as a student-centered teacher commented about the professional activities that modeled the mathematics activities. "The only way we're going to get teachers to better do this is if the teachers are put through the exact thing their kids are put through. So that they can develop the concept too. And when they get that kick then they're going to understand what that kick does to the kid" (Joanne, March 2001; p. 9). Joanne reported the benefit of actually experiencing the exploration, whereas Sally, classified as a curriculum-centered teacher, countered that opinion and sees no value for teachers working through the tasks to analyze their own or their students' thinking. "I don't know that all the time we should have to do the problem . . . I mean the kids actually have to do it. But for all of us to sit there and do that, I think it's kind of a waste of time" (Sally, April 2001; p.2). The student and curriculum-centered teachers have different opinions about the effectiveness of some of the professional

activities and the importance of understanding students' thinking. However, observing other teachers was an activity both groups agreed would help to improve their practice.

#### Hypothesis 4

Teachers with an average number of mathematics courses responded significantly more positive to two of the four M1 activities than teachers with less or more university mathematics courses. The M1 activities are focused on students' mathematical thinking and strategies, and are more content focused than the other activities. Ann, a teacher who has completed less than the average number of university mathematics courses within the group said,

People who are really comfortable . . . assume that you have a higher level of knowledge than you have. So as much as it's been explained to me a little bit, I don't feel that I have all the pieces. At least not so I feel confident . . . the gap is, in teaching it to the kids . . . (I) don't have the repertoire of different angles to come at it. (Ann, April 2001; p.9)

Leslie, a sixth grade teacher with an average mathematics background shared how teachers with an average mathematical background can feel comfortable learning from those with more content expertise. During this activity, the curriculum was modeled for the teachers as students.

We as 6<sup>th</sup> grade teachers . . . would solve something totally different, very visual. We were drawing those little pictures and things like that. And some of the 7<sup>th</sup> and 8<sup>th</sup> grade teachers were, like, not laughing at us, but laughing because of the different way(s). Where they approached a problem, maybe algebraically, with a formula, we approached it totally different. Probably how our students would. Because we weren't as familiar with the math behind it as they were. So we were trying to approach it in a totally different way. And we learned a lot from each other in doing that. (Leslie, April 2001; p.2)

The teacher who had completed more university mathematics courses was not as inspired by the sessions focused on strategies and content development. Eileen reported, "There was a lot more time spent doing, you know, catching up the non math people and telling them "This is what we're doing, this is why we're doing it" (Eileen, March 2001; p.12). The interviewed teachers' mathematics background seemed to be a significant determinant of their responses to various activities with student work, student strategies, and working through mathematical tasks.

#### Conclusions

Teachers' entry characteristics do seem to influence their response to professional development activities. This study found that inexperienced teachers have a great

faith in teacher collaboration, despite some negative experiences. In addition, teachers' views of mathematics teaching are predictive of their responses to professional development activities focused on reform-minded curriculum. The teachers who view teaching as student-centered consistently rated activities more effective than teachers with a curriculum-centered view of learning. Finally, this study determined that teachers' mathematics background is a significant determinant of their reactions to particular activities focused on students' mathematical thinking and development of the curriculum.

Although the findings suggest some specific relationships, the interview responses indicate that the teachers might not hold these relationships in such a specific way. Their comments often drifted away from the goal of attention to students' thinking and addressed more general goals, such as "improved instruction." This suggests that teachers also might have responded on the survey in terms of an activity's general benefit rather than its influence on their attention to students' thinking.

During the teacher interviews it became apparent that the teachers were not focused on understanding students' thinking and did not view it as a primary goal of the professional development program. Despite the reform-minded curriculum and the emphasis of the NCTM Standards during their training this goal was not explicit for the teachers as they came to understand the curricula and their shifting teacher role. The teachers focused their responses on other more general instructional concerns. I have argued elsewhere that teacher learning goals need to be made the focus of professional development for the developers and for teachers as learners (Cwikla, 2002). Otherwise the purpose of the professional activities remains at the "improve student learning" level and ongoing teacher learning remains loosely defined and it is difficult to assess a professional program's effectiveness.

Next steps for investigation of the four mechanisms might move beyond the teacher self-report data and into the classroom to investigate teachers' use of students' thinking in their practice. The growing shortage of properly trained teachers, efforts to reform mathematics education, accountability mandates in the United States, and impoverished teaching compel intense examination of professional development and the ways to enhance existing teaching. The ultimate goal is to improve the learning environment for students, and this should begin by improving the learning environment for teachers.

## TEACHER LEARNING IN THE PROFESSIONAL TEACHING COMMUNITY CONTEXT

Chrystal Dean  
Vanderbilt University  
chrystal.dean@vanderbilt.edu

Kay McClain  
Vanderbilt University  
kay.mcclain@vanderbilt.edu

Current efforts at teacher professional growth focus on the need to support the development of professional teaching communities that can both nurture and sustain generative growth (Franke & Kazemi, 2001; Nelson & Hammerman, 1996; Wilson & Berne, 1999). Secada and Adajian (1997) assert that mathematics teachers' professional communities provide an important context for understanding the nature of teachers' practices, change, and learning. This creates a need for mathematics educators to better understand the nature of professional teaching communities in order to understand the process of mathematics teachers' learning and how to support it.

The purpose of this paper is to explore the usefulness of the professional teaching community as a context in which to support teacher learning. In doing so we will explicate ways to cultivate teacher learning in the context of professional teaching communities through the use of a conjectured learning trajectory. The usefulness of a conjectured learning trajectory in supporting and organizing students' learning of significant mathematical ideas is made evident in the literature (Cobb & McClain, 2001; Gravemeijer, 1994; Simon, 1995). We maintain that this construct is useful for supporting teachers' learning in the context of a professional teaching community. As with the use of conjectured learning trajectories in conjunction with classroom teaching experiments, the benefit is the ability to test and revise a conjectured learning trajectory for teachers within a professional teaching community to learn how to best support and organize teachers' learning.

In the following sections of this paper, we start by clarifying our assumptions about what constitutes a professional teaching community. We then propose a conjectured learning trajectory for teachers in a professional teaching community and delineate the means of supporting the learning that emerges along that trajectory. We conclude by discussing how a focus on student thinking permeates the conjectured learning trajectory and the means of support.

### **Defining a Professional Teaching Community**

In order to clarify our assumptions about what distinguishes a professional teaching community from a cohort of teachers, this section provides a brief synopsis of the literature on community, professional community, and professional teaching community. Using the salient features from this literature, we frame four characteristics of a professional teaching community that we find most useful for describing what constitutes a professional community.

Bellah, Madsen, Sullivan, Swidler, and Tipton (1985) specify that a community is “a group of people who are socially interdependent, who participate together in discussion and decision making, and who share certain practices that both define the community and are nurtured by it” (p. 333). Secada and Adajian (1997) define community as a group of people who have organized themselves for a shared purpose. “They adopt or are assigned formal and informal roles, they organize additional structures (such as times for meeting and planning) as needed, and they take actions—all in order to achieve their purposes” (p. 194). This shared purpose aligns with Wenger’s (1998) concept of a joint enterprise in that it is a negotiated venture “produced by participants within the resources and constraints of their situations” (p. 79). More than merely a stated goal, this joint enterprise creates a sense of mutual accountability that becomes an integral aspect of the practice of the community. Besides group members being accountable to each other for working toward their common purpose, what we find most useful about these definitions is the idea of the practices of the members as a central part of the community. This is supported by Wenger’s (1998) notion that practice not only determines the formation of community, but also learning of the participants within that community.

As we define these enterprises and engage in their pursuit together, we interact with each other and with the world and we tune our relations with each other and with the world accordingly. In other words, we learn. Over time, this collective learning results in practices that reflect both the pursuit of our enterprises and the attendant social relations. These practices are thus the property of a kind of community created over time by the sustained pursuit of a shared enterprise (p. 45).

In order to differentiate between a professional community and other forms of communities with a shared purpose, Secada and Adajian (1997) claim that a professional community’s members share a common base of specialized knowledge. This specialized knowledge is what sets the professional community apart within larger society. The members of a professional community have the autonomy to make decisions that fall within their specialized knowledge that outsiders do not have the power to make. For example, acceptable decorum inside a courtroom is established and enforced by members of the law profession, not by outsiders with no knowledge of the practices of the law community. Senior members of a professional community mentor and evaluate the practices of new members. A shared sense of identity, common values, collective role definitions, and a communal language stem from the practices that result from the shared specialized knowledge specific to a professional community (Grossman, Wineburg, & Woolworth, 2000).

According to Grossman, et al., a professional *teaching* community is set apart by the following features: (1) teachers acknowledging and understanding differences among members and using this recognition of diversity to cultivate the understand-

ing of the group as a whole, (2) teachers coming to recognize the interrelationships of teacher and student learning and the ability to use their own learning as a resource to explore more deeply issues of student learning, curriculum, and teaching, and (3) teachers willingness to take on the responsibility for their colleagues' growth and development.

Using a compilation of the aspects from the literature on community, professional community, and professional teaching community we propose four characteristics that we find salient for the purpose of distinguishing a professional teaching community from a cohort of teachers. The first characteristic of a professional teaching community is a shared sense of purpose specific to what students are to learn. Similar to Wenger's (1998) joint enterprise and Secada and Adajian's (1997) shared purpose, this is a negotiated venture "defined by the participants in the very process of pursuing it" (Wenger, 1998, p. 77). The goal would be that a professional teaching community is centered on a common enterprise dealing specifically with student learning. For example, this shared purpose may be supporting students' learning of important mathematical concepts as opposed to solely memorizing procedures (cf. Thompson, Philipp, Thompson, and Boyd, 1994).

The second characteristic of a professional teaching community is teachers using their own learning as a resource in a concentrated teamwork endeavor to support students' learning. This characteristic follows Secada and Adajian's (1997) concept of teachers' coordinated effort to improve student learning where teachers are motivated to work together and set aside personal prerogatives in favor of the shared purpose. However, what we think is an important addition is Grossman et al.'s (2000) idea of teachers coming to recognize the interrelationships of teacher and student learning and the ability to use their own learning as a resource to explore more deeply issues of student learning, curriculum, and teaching.

We take the third characteristic of a professional teaching community from Secada and Adajian's (1997) notion of collaborative professional learning where teachers work together to learn about and improve their practices. Teachers challenge and support each other to clarify thinking and justify their pedagogical arguments in terms of students' reasoning. This is similar to Grossman et al.'s (2000) characterization of teachers' willingness to take on responsibility for their colleagues' growth and development. Another useful concept in collaborative professional learning is what Wenger (1998) calls mutual engagement where interactions build off of the engaged diversity of the members of the community. Grossman et al. expand on this stating participants acknowledge and understand differences among members and use this recognition of diversity to cultivate the understanding of the group as a whole. Because of the diverse knowledge of the participants of the community, it becomes important to know how to give and receive help, instead of individuals trying to know everything.

The fourth characteristic of a professional teaching community is a developed and communal repertoire of resources that is specific to the practice of the community.

This characteristic is developed from Wenger's (1998) concept of a shared repertoire that is produced or adopted by the community in the course of its existence and becomes a part of its practice. The elements of a repertoire "gain their coherence not in and of themselves as specific activities, symbols, or artifacts, but from the fact that they belong to the practice of a community pursuing an enterprise" (p. 82). Since this communal repertoire is developed during the process of the collaborative, coordinated effort to pursue a shared purpose, it is specific to the professional teaching community and this shared purpose. For example, if the shared purpose is supporting of students' learning of mathematical concepts the repertoire may include, but not be limited to: knowledge about student reasoning within a certain content domain, discourses that support this student reasoning, and tools developed to support and organize student learning.

### **Conjectured Learning Trajectory and Means of Support for a Professional Teaching Community**

Simon (1995) describes a reflexive relationship between a teacher's task selection and consideration of students' thinking that might emerge as they participate in those tasks. "The consideration of the learning goal, the learning activities, and the thinking and learning in which students might engage make up the *hypothetical learning trajectory*" (p. 133). The teacher creates an initial learning goal and plan for instruction, which must be continually modified as students engage in the planned activities. This notion of a hypothetical learning trajectory is similar to Gravemeijer's (1994) description of developmental research in mathematics education. According to Gravemeijer, the researcher starts with an anticipatory thought experiment where he or she tries to envision how the proposed teaching-learning process might be realized. During this thought experiment, the researcher develops conjectures about the course of students' development as well as the means of supporting it. Cobb and McClain (2001) use the notion of a conjectured learning trajectory when conducting classroom teaching experiments using coherent instructional sequences. They note that

conjectures about both a learning route and the means of supporting development along it are provisional and are tested and modified on a daily basis as we make local pedagogical judgments in the classroom. At the same time, the conjectured trajectory serves to guide the local decisions that lead to its revision. (p. 213)

Simon, Gravemeijer, and Cobb and McClain each discuss the merits of using a conjectured learning trajectory to support and organize the learning of students. In contrast, Cobb and McClain note that the notion of a conjectured learning trajectory is a very useful construct when dealing with the learning of teachers and the means of supporting that learning. We concur with their hypotheses and propose the development of a conjectured learning trajectory for a professional teaching community with

a learning goal of teachers justifying their pedagogical decisions in terms of students' thinking.

### Conjectured Learning Trajectory

In proposing a conjectured learning trajectory for a professional teaching community we take as a starting point *making current teaching practices problematic*. Teachers need a reason to want to change the current way they teach mathematics. Teachers can be motivated to transform their practice by seeing that their current form of practice is not the optimal choice for supporting the learning of their students (Cobb & McClain, 2001).

Once teachers acknowledge the problematic nature of their practice, they are motivated to learn more in order to assist their students' learning. For teachers to understand student thinking and the best way to support student learning of significant mathematical ideas they must have a deep understanding of the mathematics they teach (Bransford, Brown, & Cocking, 2000; Ma, 1999; Shulman, 1986). This knowledge of mathematical content is a necessary but not sufficient aspect of teaching math for understanding. Teachers must also have knowledge of students' diverse ways of reasoning about the math content and the pedagogical methods for supporting the students' learning of the mathematics. Therefore, the next step in the conjectured learning trajectory is *cultivation of pedagogical content knowledge* (Shulman, 1986, 1987). Pedagogical content knowledge entails the merging of content and pedagogy, as well as teacher's knowledge of students' cognitions in specific content areas (Bransford, et al., 2000).

As teachers in the professional teaching community work together, they can use each other as a resource to further develop their pedagogical content knowledge. This *collaboration* also allows teachers to build from the diversity of experiences and levels of expertise of members of the professional teaching community, which in turn can promote the de-privatization of practice. Instead of working in isolation, teachers can confer with colleagues when making pedagogical decisions.

In order to support student learning, teachers are motivated to change their practice, develop pedagogical content knowledge, and collaborate with peers. This builds to the conjectured end point of the learning trajectory: *student thinking to be used as the justification for pedagogical decisions* made by members of the professional teaching community. Meaning, as teachers plan for lessons, design tasks and assessments, and facilitate classroom discourse, they make and justify their decisions based on student thinking.

### Means of Supporting Emergence of Conjectured Learning Trajectory

Part of the process of developing a conjectured learning trajectory for a professional teaching community is speculating about the means of supporting the teachers' learning along the conjectured learning route. Therefore, in this section of the paper

we outline possible means of support for making teachers' current practices problematic, cultivating teachers' pedagogical content knowledge, promoting teacher collaboration, and justifying pedagogical decisions in terms of student thinking.

### **Making Current Teaching Practices Problematic**

Cobb and McClain (2001) describe one possible method for achieving a state of disequilibrium where teachers see their current practices as problematic in the use of video-recordings of interviews with students. Two sets of parallel tasks were presented to first-grade students being interviewed. One set of tasks followed the format of the students' traditional math textbooks with problems presented such as  $5 + 7 =$  or  $14 - 9 =$ . The other set was "designed to draw on the students' pragmatic, out-of-school reasoning" (p. 209). For example, students were asked to answer the following question: *If there are fourteen horses in a barn and nine of them come outside, how many will be left in the barn?* What made these interviews so powerful was that students solved the two sets of tasks using radically different methods often resulting in different answers although the tasks presented used the same number combinations. Consequently teachers focused on the beliefs the students had developed as a result of their traditional mathematics instruction, perceived those beliefs as detrimental, and therefore had a motivation for contemplating the revision of their instructional practices.

The point here is not the promotion of the use of interviews in teacher learning per se, but the use of a catalyst that highlights student thinking therefore creating a conflict that motivates teachers to want to change their current practices. We would conjecture that the most powerful of these catalysts would involve interactions with teachers' own students, since teachers are intimately familiar with their own instructional activities and norms established in their classrooms. If a state of disequilibrium can be established as a result of working with students with which they are familiar, the teachers will be more likely to equate this to consequences of their personal teaching practices instead of student deficiencies.

### **Cultivating Pedagogical Content Knowledge**

Pedagogical content knowledge is more than knowledge of general teaching methods or knowledge of a particular subject matter. Teachers with strong pedagogical content knowledge know the structure of their disciplines. This knowledge "provides them with cognitive roadmaps that guide the assignments they give students, the assessments they use to gauge students' progress, and the questions to ask in the give and take of classroom life" (Bransford et al., 2000, p. 155).

Within the professional teaching community, teachers' comparing with other teachers what they notice about student work, how they interpret it, and how they evaluate the quality of the work creates opportunities to support the cultivation of pedagogical content knowledge. For example, Franke and Kazemi (2001) col-

laborated with a teacher workgroup community where the main goal was teachers coming together to share and attempt to make sense of their students' mathematical thinking. They described student work as the artifact used to "focus the conversation, bring teachers' rich experiences and histories into the conversations, and create connections between professional development and other aspects of teachers' work" (p. 13-14). More specifically, they chose to use student work from the teachers' own classes. The teachers posed an agreed upon mathematical problem to the students in their classes. The intent was to choose a problem "that allowed conversation to develop around similar mathematical ideas and permitted a range of entry points to accommodate different mathematical understandings" (p. 14). The teachers' task at the next workgroup session was to share their students' work, generate a group list of strategies used by their students, and then rank the list according to sophistication of students' mathematical understanding. "Teachers detailed the thinking of a number of students in relation to each other, they described the circumstances within which student mathematical thinking occurred and they used the details of student thinking to support their conversations about the issues surrounding the teaching and learning of mathematics" (p. 15).

This use of student work fits with Wenger's (1998) argument that an artifact can provide a focus for the negotiation of meaning, which in turn supports the learning of the community. In other words, concentrating on student work provides a tool the teachers can use to justify conjectures about the teaching and learning of mathematics, which subsequently supports the learning of the professional teaching community. It is important to note here that this use of student work was a catalyst for focusing on student reasoning, probing the mathematics of the problem itself, and delineating ways to support the students in moving forward with their mathematical thinking. We agree with Ball and Cohen (1999) that simply looking at students' work will not guarantee that improved ways of examining and interpreting such work will automatically result. It would be essential for teachers to develop and debate conjectures about what to observe, ways to describe what is observed, and formulations of what is sufficient evidence for any given claim.

Teachers could explore the thinking that the assignments called for by doing it themselves and then comparing their work. Both would create opportunities for teachers to discern the content entailments of assignments and to learn some of the content. They could learn how unpacking a student task can help teachers delve into the associated or underlying ideas. Discussing the assignment with one another would enable them to see others' paths and connections and others' ways of working and solutions. Such discussion would both expand teachers' own understanding and extend their view of the terrain. (p. 26).

In order for teachers to focus on and debate student work, they must first investigate and study the mathematics required in the work. This allows them to better

understand students' diverse reasoning and solutions. Armed with the knowledge of the math content and a better understanding of student thinking, teachers can concentrate on pedagogy that supports students' learning of the mathematics. Therefore, student work can serve as a catalyst to support the cultivation of pedagogical content knowledge within a professional teaching community by pushing teachers to discuss the mathematical content involved, attempting to understand students' thinking in their diverse solutions, and conjecturing about teaching practices that support students' learning.

Teachers' looking at the student work together hints at the benefits of having teachers collaborate. A goal would then be to further develop collaboration in the professional teaching community so that it becomes more than just working with another person. Instead collaboration becomes teachers engaging in precise talk and debate about teaching practices where they rely on each other as learning resources. In the following section, we will outline one way to support teacher collaboration through joint lesson plan development.

### **Promoting Teacher Collaboration**

Another opportunity for teacher learning within the professional teaching community is teacher collaboration in pursuit of a shared goal with a focus on student thinking. Working together towards a shared purpose gives members of the professional teaching community a collective responsibility for each other's learning as well as student learning. "This responsibility might include making contributions to group discussions, pressing others to clarify their thoughts, engaging in intellectual midwifery for the ideas of others, and providing resources for others' learning" (p. 55). Instead of teachers working through pedagogical issues in private, they would have the opportunity to encounter the diversity of other teachers' views and interpretations. Not only could teachers learn about teaching, learning, and mathematics, they would develop "new ways of thinking and reasoning collectively as well as new forms of interacting interpersonally" (Grossman et al., 2001, p. 46).

Promoting the collaboration of teachers can be supported as teachers plan lessons together in a fashion similar to the notion of the Japanese lesson study as described by Stigler and Hiebert (1999). According to Stigler and Hiebert, groups of teachers meet regularly over a period of time ranging from several months to a year to work on designing, implementing, testing, and improving one or several lessons.

The first step of a lesson study group is to define a math problem that will motivate and direct the work of the group. This problem usually comes from issues the teachers have identified from their interactions in their own classrooms that have been a challenge to them and/or their students. The second step of the Japanese lesson study is actually planning the lesson, which can take as long as several months. The third step involves one teacher teaching the lesson with the other members of the group leaving their own classrooms in order to observe the lesson being taught. Step four is

the evaluation of the lesson and reflection on its effect. Step five is the revision of the lesson. Based on the teachers' observations and reflections of student understandings (or misunderstandings), the lesson is revised by the group.

This is not to say that an exact replica of the Japanese lesson study process will work in the United States as our education system differs from the Japanese system in significant ways, but there is much to be learned from the lesson study concept. As the teachers collaborate "to improve instruction, teachers are able to develop a shared language for describing, and analyzing classroom teaching, and to teach each other about teaching" (p. 123), thus supporting the learning of the professional teaching community.

As all members of the professional teaching community are invested in the outcome of the lesson, the collaboration during the lesson study creates an avenue for teachers to begin justifying the decisions they make about the lesson in terms of student thinking. The culminating goal of the conjectured learning trajectory we have proposed is teachers justifying decisions based on student thinking, not just decisions when planning the lesson, but all decisions such as task selection, classroom environment, discourse, and all forms of student assessment. Next we will discuss means of support specifically designed to promote teachers justifying all decisions based on student thinking.

### **Justifying Pedagogical Decisions in Terms of Student Thinking**

The means of support discussed previously in pursuing a conjectured learning trajectory within a professional teaching community that culminates with teachers justifying pedagogical decisions based on student thinking can move the professional teaching community towards this endpoint. Two constructs that support the further development of teachers in the professional teaching community making and justifying their decisions based on student thinking are Simon's (1995) Mathematics Teaching Cycle and Cobb and McClain's (2001) enacting of an instructional sequence.

Previously in this paper we discussed Simon's (1995) notion of a hypothetical learning trajectory where teachers plan tasks based on their knowledge of content and student thinking and then make modifications to that task as a result of student interpretation of and interaction with the task. Simon claims that this modification happens as the teacher develops new understandings of the students' knowledge constructions by observing and communicating with the students while they are engaged in the activity. The hypothetical learning trajectory gives rationale to the teacher's choice of a particular instructional design based on how the teacher perceives that learning might proceed. There is a difference between the hypothetical trajectory and the actual path taken.

As the teacher interacts with and observes the students, the teacher and students collectively constitute an experience. This experience by the nature of its social constitution is different from the one anticipated by the teacher. Simultaneous with and

in interaction with the social constitution of classroom activity is a modification in the teacher's ideas and knowledge as he makes sense of what is happening and what has happened in the classroom. (Simon, 1995, p. 137)

Simon expands on this idea by commenting on the continuous engagement of the teacher in adjusting the learning trajectory to better reflect what he or she has learned about the students. Sometimes this calls for a minor adjustment, while at other times the entire focus of the lesson might be changed. Simon presents a schematic model for this decision making process called the Mathematics Teaching Cycle as shown in Figure 1 below.

Cobb and McClain (2001) identify with this model calling it "enacting an instructional sequence" (p. 215). Cobb and McClain in collaboration with Koeno Gravemeijer have developed coherent instructional sequences aimed at significant mathematical concepts. Cobb and McClain point out that when pursuing an instructional agenda aimed at mathematical understanding, one must be explicit about the overarching mathematical ideas of the instructional sequence. Once the overall instructional goals are delineated, they orient the formulation of a conjectured learning trajectory that itself serves as the backdrop against which local pedagogical judgments are made. The teacher and students create the *actual* learning trajectory as they interact in the classroom. The teacher has a pedagogical schema, "an overall instructional intent and an envisioned means of achieving it" (p. 215), which provides a sense of direction that is continually modified during the act of teaching. Cobb and McClain assert that teaching must be informed by a relatively deep understanding of students' mathematical thinking and "classroom discussions should be justified in terms of their contributions to the fulfillment of an evolving instructional agenda as indicated by the mathematical significance of the issues that emerge as topics of conversation" (p. 214).

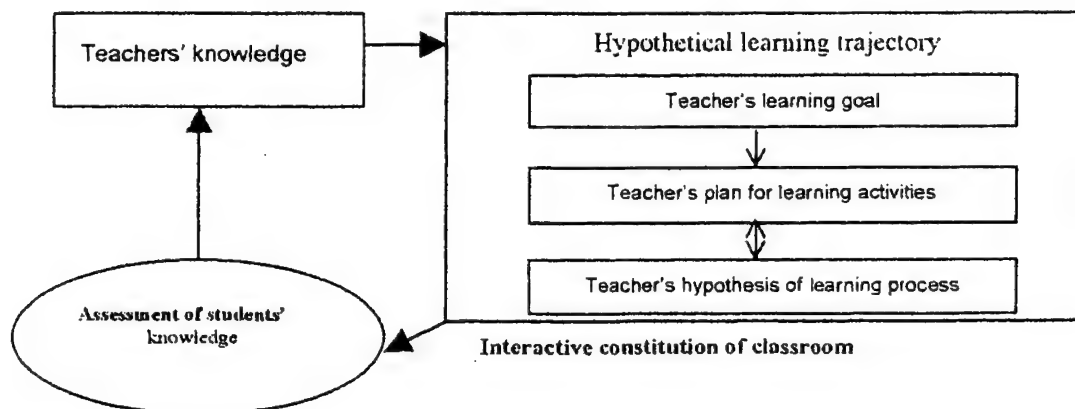

Figure 1. Mathematics teaching cycle (abbreviated).

Simon's (1995) mathematics teaching cycle and Cobb and McClain's (2001) enacting instructional sequences highlight the intersection of teachers' knowledge of subject matter, pedagogy, and student thinking. Teachers are not carrying out the plans and intentions of others. Rather, teaching is viewed as a generative process of idea-driven adaptation where teaching becomes an occasion to deepen one's understanding of the mathematical concepts that become the focus of classroom discussions, of students' reasoning, and of the means of supporting its development. Since the pedagogical decisions made by the teacher have a reflexive relationship with the contemplation of student thinking that might emerge as a result of those decisions, justifying pedagogical decisions in terms of student thinking is supported.

### Conclusion

Since teaching math for understanding presumes the importance of the teachers' understanding of students as learners, permeating through this conjectured learning trajectory is the focus on student thinking. We would argue that this is paramount to the effectiveness of the conjectured learning trajectory within the professional teaching community. The underlying assumption of the support structures mentioned is a focus on students' thinking to initiate shifts. Each means of support throughout the conjectured learning trajectory builds on this idea of focusing on students' thinking. The interviews used as a catalyst to make current teaching practices problematic will not be successful unless teachers attend to the fact the students are thinking differently about the two tasks that are presented to them. This alone does not mean the teachers will attend to student thinking. Even though the teachers notice a difference in the students' thinking, they could make changes in their practice without focusing on student thinking. Therefore, it is important that this focus on student thinking permeates the conjectured learning trajectory and its means of support.

This focus on student thinking is evident when trying to cultivate pedagogical content knowledge. In fact, by definition, pedagogical content knowledge calls for teachers' knowledge about how students reason about mathematics. The conjectured means of support for cultivating pedagogical content knowledge was examining student work. As teachers examine student work, the support mentioned for cultivating pedagogical content knowledge, they must attend to more than just the mathematical content and whether or not the student produced the correct answer. The main focus of looking at student work is debating students' thinking behind the diversity of their answers. In order to support students' learning of the mathematical ideas, teachers must first attempt to understand students' reasoning. Teachers can then build from the students' thinking about the problem to support students' learning of the mathematics instead of trying to "fix" the students ways of doing the problem. Since teachers are looking at the student work together they can hold explicit conversations about their interpretations of student thinking and how to support it.

As collaboration develops within the professional teaching community, teachers can begin to hold each other accountable for focusing on student thinking. What makes the lesson study process so valuable as a support here is its “unrelenting focus on student learning. All efforts to improve lessons are evaluated with respect to clearly specified learning goals, and revisions are always justified with respect to student thinking and learning” (p. 121). As teachers plan, teach, and revise a lesson together, decisions about modifications to the lesson are made based on students’ thinking.

Focusing on student thinking when planning is a fundamental shift in reasoning about teaching. However, the conjectured ending point of this conjectured learning trajectory is for all pedagogical decisions to be made in terms of students’ thinking. A focus on students’ thinking should permeate all aspects of teaching: task selection, planning, classroom environment, discourse, informal assessment, formal assessment, etc. One of the strengths of The Mathematics Teaching Cycle and enacting coherent instructional sequences is their focus on having a mathematical agenda while attending to students’ thinking. This means decisions made are based on student thinking, but there is a mathematical agenda and thus a sense of direction.

Since the focus on students’ thinking is so important to the effectiveness of the conjectured learning trajectory within the professional teaching community, it would need to be a focus of the analysis of the conjectured learning trajectory. This is not to say one would analyze whether the conjectured learning trajectory was successful based on whether or not teachers made a shift to focusing on student understanding. Instead, the analysis would focus on understanding where these shifts occurred and how they were supported. This would then be a rationale for modifications to the conjectured learning trajectory. This cyclic process would produce a modified conjectured learning trajectory that takes account of prior learning. In this way, teacher learning and learning about teacher learning feed forward to inform decisions in a new conjectured learning trajectory.

## TEACHING PLACE VALUE: SEEKING TO RECEIVE KNOWLEDGE, BUT LEARNING TO REASON

Rapti de Silva  
California State University, Chico  
rdesilva@csuchico.edu

This report is part of a study that analyzed issues in improving Sri Lankan primary teachers' learning and teaching of mathematics in the context of a distance based course for teachers (de Silva, 2001). Three questions frame the research reported in this paper: How do teachers set about learning and teaching mathematics? What aspects of the distance program facilitate their understanding and what fail? To what extent are they supported in their professional development? The questions I proposed called for qualitative research methods where one "begins with an area of study and what is relevant to that area is allowed to emerge" (Strauss & Corbin, 1990, p. 23) as theory grounded in the respondents' experiences. In particular, I used a critical ethnographic approach where the researcher raises her voice to "speak *to* an audience *on behalf* of [her] subjects as a means of empowering them by giving more authority to the subjects' voice" (Thomas, 1993, p. 4, *italics in original*). In this paper I analyze issues related to a second grade teacher's teaching of place value as the problem emerged and was explored in the research process.

### Rationale for and Significance of the Research

Research from around the world indicates a dearth of teachers qualified to teach mathematics (Arnold, Shiu & Ellerton, 1996). The situation is crucial at the primary level where teacher education is given least priority (UNESCO, 1992). In the 1980s the situation in Sri Lanka was similar with a large number of untrained primary teachers (Tatto, Nielsen, Cummings, Kularatana & Dharmadasa, 1991; UNESCO, 1990). By the time of my study in 1998, a 3-year distance primary teacher education program begun in the mid 1980s was being phased out and short-term distance courses were being implemented to provide continuing professional development for primary teachers. Based on quantitative data and analysis of surveys, Tatto et al. (1991) found that graduates of the 3-year program showed a significant drop in both their mathematics knowledge and pedagogical skills after leaving the program.

Although the latter study does not specify the kinds of mathematics knowledge and pedagogical skills assessed, the teaching of place value concepts is fundamental to the primary mathematics curriculum. A number of studies document U.S. elementary teachers' understanding of place value as limited to procedures and sparse in connections to related concepts (Ball, 1991; Leindhart & Smith, 1985; Ma, 1999; Ross, 2001). Ma (1999) also documents Chinese elementary teachers' "profound understanding" of place value concepts and identifies aspects of their educational experience that she believes supports the development of such an understanding. On the other hand, the research reported in this paper, while analyzing one teacher's limited understanding of

place value, identifies aspects of her experience that could similarly limit other teachers' understandings.

Student collaboration in planning and implementing programs is a critical in the success of distance teaching and learning of mathematics and mathematics education (Arnold et al., 1996). Given the lack of empowerment accorded to and felt by many, mainly female, primary teachers (UNESCO, 1990a), even if programs promote collaboration, due to prior experiences, teachers may not actively collaborate. Hence, I believed that research on issues faced by primary teachers who are distance learners should be geared to social change through some form of action research, where the researcher works with teachers and encourages them to reflect on and share their practice, voice their concerns, collaborate to be heard, and be active in their own learning. The above "participatory research model" has been identified as specially suitable for the way women come to know, where the validation of their experience is the basis for their making connections (Belenky, Clinchy, Goldberger & Tarule, 1986).

In particular, I believed it would be useful to delve more deeply into the reasons for the phenomenon identified by Tatto et al. (1991) using qualitative methods of data collection and analysis. Such research is best accomplished using extended participant observation as in ethnography (Eisenhart, 1988). The survey of teacher education on which the UNESCO (1990a, 1990b) reports were based recommended ethnographies as a form of research study, but found that few existed in the member countries of the Asia Pacific region surveyed and none in Sri Lanka.

### **Conceptual Framework**

In conceptualizing my research, I used Saxe & Bermudez's (1996) emergent perspective where learning is seen as a process of evolving goals influenced by prior experiences, social interactions, activity structures, and cultural artifacts. The socio-cultural perspective offered by Crawford (1996) influenced my analysis of respondents' reflections on their teaching of mathematics:

When activity is considered an important factor in the construction of knowledge, a number of questions are raised. How does a learner subjectively experience, or interpret, his or her own action, and the actions of others in an educational setting? What are the relationships... between the cultural context of a learning activity, the behavior of the learner, the learner's subjective experience of the action, and the qualities of the cognitive and affective activity that occur? (p. 132)

Given my questions and the relevant literature, I chose critical ethnography as an appropriate research method. Of the variants of critical ethnography discussed by Thomas (1993), I used a participatory approach where:

researchers ... become active in confronting explicit problems that affect the lives of the subjects – as defined by the subjects – rather than remain passive

recipients of “truth” that will be used to formulate policies by and in the interests of those external to the setting. (pp. 28-29)

As I conceptualized my study, I began to reflect on issues of voice, identity, my role as a researcher, and my critical ethnographic approach. Given my questions and female respondents, Belenky et al.’s (1986) research provided a framework for analysis that complemented my theoretical perspectives and critical approach. In their research, Belenky and colleagues identified the importance of *voice* – of listening, hearing, and speaking – and of *connection* – of belief, trust, and nurture – in the way women come to know. In my analysis, I tried to hear my respondents’ different “voices” and to relate their voices to how they interact with others and their ways of knowing.

### Data Collection

My study investigated issues relevant to Sri Lankan primary teachers’ learning and teaching of mathematics in the context of the distance-based course Continuing Education in Primary Mathematics (CEPM) offered through the National Institute of Education (NIE). As outlined in the proposal (National Institute of Education, 1997), the objective of the course was to improve primary teachers’ knowledge and understanding of the content they teach and the way they teach mathematics.

The 1-year course began in November 1997. I conducted fieldwork throughout 1998 (the calendar year coincides with the academic year) at the NIE, two primary schools, and three tutorial centers. From April to June I lived “on-site” near the primary school L where the second grade teacher Thushara and two of her colleagues – Kamala and Prema, also respondents in the larger study – taught. I conducted follow up visits in October and November. This report is based on data from the following sources: classroom observations; teacher interviews; observations at the tutorial center where CEPM participants met thrice a month for discussion and assessment; interviews with tutors and officials at the NIE; and analysis of the print based course modules.

### Data Analysis

A very important topic in primary mathematics, first introduced in the Year 2 curriculum, is place value. I begin by describing a lesson that Thushara taught on place value and analyzing aspects that proved problematic. Next, I discuss some issues related to Thushara’s understanding of place value as they were revealed over the course of the study. Finally I discuss the extent to which the CEPM course helped Thushara improve her understanding of place value concepts and of how to teach it.

### A Lesson on Place Value

During my 5<sup>th</sup> week at L, Thushara taught a 3-day lesson on place-value. Since she was teaching the topic for the second time that year, the approximately 50 students (54 on the class list) were somewhat familiar with the manipulatives and representations used.

### **The Importance of Instructions**

Thushara began by asking students to take out their ekel bundles (10 sticks) and remove the string tying one bundle. Holding up a bundle, she asked "How many ekels?" When the children replied 10, she asked, "how many ekels must one add to it to get 11 ekels?" When a child answered one, she asked them to place a single ekel by the side of a bundle. Since Thushara did not say to use the least possible number of single ekels, it was unclear who understood the connection she eventually hoped to make with the numerical representation of numbers. For example, when asked to make 12, I observed at least four students who removed the string tying another bundle and counted out 12 single ekels. The children may have been better motivated by (a) asking whether they could show 11 using the least number of single ekels and (b) having them explain why they used one bundle of 10 ekels and one single ekel to do so.

Thushara drew the ekel representations (e.g., 1 bundle and 3 single ekels for 13) on the chalkboard after asking students to use their ekels to make each of the numbers 10, 11, 12, 13, and 14 respectively. After each was made, she went around checking whether students had placed ekels correctly. By 13, most students had caught on to the expectation of using one bundle and the necessary single ekels and, except for a few who I observed copying what another was doing, most seemed to make the expected representations. The children continued making ekel representations for 15, 16, 17, 18, and 19. Many realized adding a single ekel to the last representation led to the representation for the next number.

After the children had added a single ekel to the nine single ekels and one bundle of 10 ekels to get 20, Thushara asked, "how many bundles of 10 ekels do you have?" Most answered one, while a few children said two, despite their not having exchanged the 10 single ekels for one more bundle of ten ekels. Thushara then asked if they had any single ekels and most students replied that they had 10. Given no instructions about using the least number of single ekels or the idea of exchanging 10 single ekels for one bundle of 10 ekels, Thushara's questions were probably very confusing for the students.

### **The Importance of Language**

In the above activity, after students had made 15, Thushara asked them to verbalize how they had made it. When some said that they had used five from the bundle that was untied, she said "no, you should say five ones". She then asked the entire class to repeat the following: "one bundle of 10 and five ones". As the children worked on 16, 17, 18, and 19, she asked them to verbalize what they used in a similar manner. Next, Thushara drew an ekel bundle, set it equal to ten ( $= 10$ ) then asked the children "are there any ones in 10?" When some replied no, she pointed to the zero and said "that's why we write zero here." She then asked, "how many bundles of 10 are there?" and when some replied "one" she pointed to the numeral 1 and said "that means one bundle

of 10.” I noted that while she used the phrase “bundle of 10” quite often, she did not use the phrase “single ekels.” Instead she referred to the latter objects as “ones.” This was I believe one reason for the considerable number of incorrect responses to the questions Thushara later asked of individuals. Given the students’ need to associate the concrete manipulatives with the abstract numerical representations, Thushara probably needed to be very careful and systematic in her use of language, but unfortunately she was not.

The 2<sup>nd</sup> day was spent in a similar manner representing the numbers from 1 through 20. On the 3<sup>rd</sup> day, Thushara began by writing the following on the board: Draw ekel bundles for the following: 13, 17, 10, 11, 19, and 15. While Thushara was away on an errand some students finished their work and brought it to me. Seizing the opportunity to find out how the children were thinking, I asked each to explain why they drew what they did. Many were able to explain how the numerals in the numerical representation of the number represented the number of single ekels and the bundle of ekels they had drawn. However, a few students had drawn just one bundle of ekels for each number. When questioned, their response made sense given the instructions “draw ekel bundles” for numbers that were limited to the teens. Once again, the importance of using careful language struck me as being important.

### **The Importance of Variation**

After Thushara returned, she corrected the children’s work. I observed that those who had mistakes were simply sent away without asking them to explain how they were thinking or asking questions that would help the child to understand. Later, when Thushara went over the work at the board, she asked “how many say there is one 1 in 10?” All but five children raised their hands. Although Thushara did not ask any of the children to explain their reasoning, I believe that those who replied “one” did so based on the digit 1 appearing in the numerical representation of 10. Thushara then attempted to help the children understand by showing two bundles of ekels and asking “How many bundles of 10? How many ones?” to which most children replied two and zero respectively. I suspect that since these were physical objects, the children had no trouble identifying two bundles of 10, but their response of zero for the number of ones, was very likely due to the digit 1 not appearing in the numerical representation of 20. Perhaps Thushara’s lesson on place value would have been successful at least on a procedural level had she had children makes representations of 2-digit numbers other than those in the 10s where by varying the number of groups of ten in a given number she helped children make the intended connection between the concrete and numerical representations.

### **Discussion**

The extent to which the lesson helped children understand place value appeared superficial. Their learning was limited by the lack of careful instructions, language,

and variation in the activity Thushara used. As usual, Thushara based her teaching on an activity suggested in the teachers' handbook. The brief outline in the latter gave no indication of the complexity of the issues related to teaching and was thus of little pedagogical use to Thushara other than as an organizational structure. When, at the end of the lesson, students competed in two teams and were asked to identify "how many bundles of ten" and "how many ones" there were in ekel representations for different numbers between 10 and 19, the children made many errors. Although both the children and Thushara seemed to enjoy the competition very much, the focus was only on the answer being right or wrong. No explanations were required nor given. Thushara's lack of instructions about the mathematical idea behind the use of the ekel manipulatives to represent a number using the least number of single ekels and her referring to single ekels as ones were, I believe, the primary reason for most children's failure to make sense of the lesson on place value.

### **Thushara's Understanding of Place Value**

Why was it that Thushara did not give instructions to use the least number of single ekels nor explain the idea of exchanging 10 single ekels for one bundle of 10 ekels? I believe she herself was unclear about their importance.

### **Seeking to Impart and Receive Knowledge**

As I copied Thushara's drawings on the 1<sup>st</sup> day, I did so in a cursory manner, noting the idea of a bundle of 10 ekels and a given number of single ekels. Midway, however, Thushara said each bundle of 10 ekels should be drawn with nine vertical lines with the line going across representing the 10<sup>th</sup> ekel. Aware of the way we represent 5 using the tally mark system, I wondered whether Thushara thought this was how one should teach children to represent 10. I then looked closely at her drawings of ekel bundles and observed that they did in fact consist of nine vertical lines with one horizontal line across.

Later, I asked Thushara why she represented the bundle of 10 ekels in that manner. She replied that she used to draw 10 vertical lines and 1 horizontal line until a teacher supervisor had told her she was wrong. The supervisor had cited the tally mark representation of 5 and told Thushara that 10 should therefore be represented in a similar manner. I asked Thushara whether she thought children would understand the horizontal line to be an ekel or whether they would see it as the string. She said that the supervisor should know, but perhaps the tally style representation should be taught after the representation that best captures the physical objects. Thus although her original representation appeared to make the best sense to her, Thushara was still willing to accept the supervisor's knowledge as superior. Further, her style of learning was reflected in her style of teaching where explanations were not given and reasoning was not valued.

### Learning to Question and Reason

Thushara, no doubt, continued to think about the issue of meaningful representation. During the group interview the next day, as an example of erroneous thinking on the part of an authority, she repeated what the supervisor had said. The three teachers had been discussing an issue of representation in the Year 1 textbook that their tutor had pointed out was problematic for young children:

- Kamala: The thing is addition is one of the first things done in Year 1, so the error happens there. It is not us, but the big places (i.e. Ministry of Education) themselves have approved this.
- Thushara: Now yesterday in the *ekel* bundle problems. When I came to Year 2 in the beginning I used to draw 10 ekels and – in the book that’s what they show and then with a rubber band. Now the tally mark system is where we draw four and then indicate 5 like this. Mrs. J looked at my work and said, “first draw nine ekels like this and then put the 10<sup>th</sup> across like this”. That the other one was wrong. Not to teach like that again, because that is incorrect. So I said – this was when I first came – “I didn’t know, okay” and that’s what I was doing since.
- Prema: Yes, but then in reality we are not tying the bundle with the 10<sup>th</sup> ekel.
- Thushara: We aren’t, but Mrs. J said that was wrong to depict it the way it is done. She said to put nine and tie with the 10<sup>th</sup>
- Kamala: But that is wrong. The children are not going to understand that.
- Prema: Yes it’s not going to be a bundle of 10 is it? Because you will be tying with an ekel.

As the transcript proceeds, it is evident that this particular teacher supervisor had not only given Thushara bad advice, but had also made her feel humiliated. Thushara’s lack of self-confidence is obvious in contrast to the confidence of Kamala and Prema:

- Thushara: I tell you, when she said that I became really upset. I thought I’d been teaching children all wrong. So from then on, I started to draw nine and put the 10<sup>th</sup> across.
- Prema: No, no, no. I wouldn’t have accepted that as being correct.
- Rapti: I think that what you used to do, that’s what the children can follow a lot more easily
- Thushara: That was right. So I was really upset since she said “the way you do it there are 11 here.”
- Kamala: That was the string – and the children are not going to understand it as being anything other than the string. (O.C. lots of simultaneous agreement)

Prema: Then you should have asked her, “then should I get the children to have bundles of nine ekels that are tied with an ekel?”

Thushara: Yes, but see she showed me the tally mark system.

Three years later, Thushara still lacks confidence to voice her own opinion or to analyze the situation on its merits. “That was right”, not “I was right”, is how she responds to my comment about her prior representation making more sense to children. Further, while Thushara seems convinced that Mrs J. was incorrect, she also continues to explain the latter’s reasoning. Unlike Kamala, whose focus is on what the children will understand, and Prema, whose focus is on the object being represented, Thushara’s focus is on the immediacy of what the supervisor said, and how it made her feel. The tone of each teacher’s voice is also different: Kamala’s is calm and confident; Prema’s is argumentative and confident; and Thushara’s is apologetic and hesitant.

### **Reconstructing Her Understanding of Place Value Representation**

In the October interview, held 5 months after the above lesson and group interview, I asked Thushara to describe her style of teaching mathematics. She did so, using her teaching of place value as an example:

Thushara: Often it is difficult to talk and teach them something. For example, numerical representation in order to have them understand, things like manipulatives, objects – it’s not like other subjects, math isn’t – when teaching math activities are essential for helping children to understand. So when teaching math specially it is through using activities and objects that I do it.

Rapti: So usually when you start a lesson you begin with an activity or use some manipulatives?

Thushara: I don’t tell them we are learning this. I give something and through that I have them understand.

Rapti: After they do the activities what do you do?

Thushara: (pause) After they do it, I give exercises to see if they have understood it. I ask questions. I ask them to do something. For example, the ekels – from 21 to 99 is what they have this week – to teach place value. Today what I did was from 1 to 50 – took randomly. At the beginning I show them how it works so they understand. For example 21 is two bundles of 10 and one single ekel. This kind of thing must be done on their own and understood. If I was to write 20 and say this 2 means two bundles of 10 ekels and the zero means no single ekels, the children don’t understand. But when they use ekels, the children understand very well.

Thushara speaks of “single ekels” rather than “ones,” a significant difference from how she referred to the objects in the lesson I observed. Further she now has children represent random numbers from 1 to 50. Perhaps the group discussion and other intervening experiences, along with her evolving understanding as she continued to teach, helped Thushara develop a more meaningful understanding of the representations that underlie the teaching of place value. However, later in the same interview, she again speaks of the single ekels as “ones”:

Today when I asked them to make 40, they put four bundles of 10 out. When I ask them to say aloud what they have, some are unable to say they have four bundles of 10 and zero ones. But most say that. So then I show that there are no ones in what you showed. That if you add nine ones you get one bundle of 10.

Her words: “if you add nine ones you get one bundle of 10” also recall the confusion created by the supervisor.

### **Deepening Her Understanding of Place Value**

In her final interview, Thushara identified students as very good, average, and weak in mathematics based on what each could do, rather than how they reasoned. In particular, the mathematics she referred to was their procedural abilities rather than conceptual thinking. Thus it was not surprising that, although Thushara seemed to understand the problem, she did not appreciate the significance of her student Nirmala’s struggles with the concepts of money and place value being rooted in her lack of understanding the pre-number concept of the one-many relationship.

Since I sat near Nirmala’s group, I was able to observe her work. From the beginning, I noticed she tended to look at another’s work to check her own, especially for addition, subtraction and other activities involving number operations. During my 2<sup>nd</sup> week I observed Nirmala identify each of the rupees 1, 2, and 5 coins but hand over one of each to buy a toy priced at 3 rupees. In handing over the three coins for one toy, she appeared to understand the many-one-relationship but not the one-many-relationship. I noticed similar problems in her work with place value and measurement. She was one of the students who counted out single ekels when asked to represent a number.

Towards the end of the group interview, the conversation veered around to the project that the teachers were expected to do for the CEPM course and Thushara asked me to suggest what kind of a project would be good for her to do. I suggested that perhaps she could work with Nirmala citing the incident with the coins.

Rapti: Nirmala ... suppose she is adding Rs 2 and Rs 5. She has yet to understand that the one coin represents 2 rupees. So though she will identify the coins as rupees 2 and rupees 5, when added she says there are 2 rupees, because she identifies each coin as one object.

Thushara: Yes, today when I asked how many ekels were in the bundle of 10 ekels, she said there was one.

Prema: Ahh, because there is just one bundle, so it is taken as one.

Her making the connection between Nirmala's problems with the value of a coin and the number of ekels in the bundle indicates that Thushara had a good understanding and an immediate grasp of the conceptual similarity between the two situations. However, Thushara's tendency to focus on surface details and procedure, and her need to have pre-structured and detailed guidelines prevents her from building on her grasp of Nirmala's problem:

Rapti: You have at least two examples where you've identified a similar abstract thinking gap in her understanding. You could figure out pre-concepts to build on to help her understand.

Thushara: Yes. (pause)

Rapti: This has to do with the value represented by one object being more than one unit. Perhaps you need to work with objects that have some value meaning for her as a child.

Thushara: How do you get a topic out of it? They say you have to focus on a topic.

Kamala: (O.C. Reads from the handout which describes the requirements of the project) "A problem, an incident, a situation." What this would be is a situation.

Rapti: Yes, you can describe how you noticed the situation—when you did this activity you noticed her doing this and then when you did another you noticed a similar thinking problem. This is what you think is the problem: one-to-one – no

Prema: (interrupting) One-to many.

Rapti: Yes, one-to-many relation seems to be the problem the pre-number concept is lacking.

Thushara: (interrupting) She copies a lot. Looks there writes or does the same. That is a big problem. So she is not willing to think. But her Sinhala is very good. Does the work on her own, is organized, reads and writes very well. (Group Interview)

Was it that Nirmala was not willing to think, or was it that Thushara did not realize the importance of spending time having her engage in activities that help her understand the one-many-relationship? Since she does not offer any thoughts with respect to the pre-number concepts of relations and representations, the extent to which Thush-

ara realized the important developmental progression involved is not clear.

Given Thushara's emphasis on procedure in both her learning and her teaching, it was not surprising that her CEPM project focused on helping students learn a procedure rather than understand a concept. In her final interview in November, I asked Thushara to describe the ideas in her project:

Well it was about addition where carry over was not involved. Now I was telling the sirs that when children are adding  $3 + 2$  is 5, some write it in a vertical line. It's the ones who can't that you take for the project. There are eight children. 3 is here, plus sign is here, 2 is here, and then the answer 5 somewhere else. Even 100s and 10s are the same. The 100s column and 10s columns are here and the answer over here. The place value idea is not there – didn't go that far, but I just did that little.

Thushara's thinking it not important to discuss concepts of place value in adding numbers where carry over was not involved is troublesome. Since she asked students to add up to 3-digit numbers, her emphasis on procedure was compounded by her lack of helping children understand that the procedure of aligning numerals enables easy recognition of "like objects" (units, tens, and hundreds). It suggests her own concept of place value was not well connected to her concept of addition. Further, during my first week, I observed Thushara begin a lesson on addition by having the children sing a song that involved vallikukulas (a kind of bird) and rambuttan (a kind of fruit) and then asking them how many vallikukulas and rambuttans there were altogether. In my field notes I noted that addition of unrelated objects did not make much sense. Given Thushara's comments in the above transcript, it is possible that her focus on procedure had resulted in a disconnected understanding of both place value and addition.

### **CEPM's Discussion of Ideas Related to Place Value**

Despite the second module being on number and numeration systems (CEPM 102) and the third on basic operations (CEPM 103), Thushara did not develop a solid conceptual understanding of place value in the course. In CEPM 102 different numeration systems are presented separately, with brief discussions and examples of properties. Each system is further illustrated with examples of operations on numbers. On the other hand, the discussion of place value in the Hindu Arabic numeration system is extremely brief: "The value of a numeral depends on the place it holds. e.g., in the number 333, the numeral 3 represents the numbers 3, 30, and 300." A comparative discussion of the properties across the different systems would have enabled a better understanding of place value. Similarly, the discussion of basic operations in CEPM 103 focuses on set-theoretic properties and abstract definitions. Teachers like Thushara would have benefited from activities that helped them construct a concrete and meaningful understanding of the operations and how place value is implicit in why our algorithms work.

In particular, no activities that help teachers model and discuss the structure of the Hindu Arabic numeration system and our computational algorithms are presented in either of the modules. Given their use in the primary classroom, ekel based manipulatives extending beyond the bundles of 10, could have provided teachers with the tools to start understanding the concepts behind the description of place value. An activity structured with the emphasis on always exchanging groups of 10 similar smaller objects for 1 bigger object could have helped teachers to better understand that the manipulatives do not themselves have inherent mathematical meaning. Activity whose emphasis was on understanding the importance of the careful instructions that should accompany a child's use of manipulatives would have enabled these teachers. But, as with most modules, the teachers were not asked to think about teaching their students. Further, given Thushara and other teachers' reliance on the very limited activity outline in the teachers' handbook, the CEPM modules could have helped teachers to collaborate on expanding and supplementing their limited resources. However, as discussed in the larger study (de Silva, 2001), the modules rarely asked teachers questions that required them to go outside the given module let alone make connections to other modules. Overall, the course as implemented did little to help primary teachers improve their understanding of the primary mathematics content or pedagogy, despite that being its proposed objective.

### **Supporting the Emergence of Subjective Knowing**

Thushara's narrative of learning and teaching the primary mathematics concept of place value highlighted issues that may affect other primary teachers. Given that Thushara was the one teacher in my study who diligently followed the self-study aspect of each module, her experience provided a way in which I could analyze the CEPM course by focusing on how successful it was in helping teachers improve their understanding of the concepts they teach, in the context of their professional lives. During my study, Thushara's voice and ways of knowing seemed most similar to those of women Belenky et al. (1986) describe in their chapter on "Received Knowledge: Listening to the Voices of Others" as follows:

She "learns" the material; that is she stores a copy of it, first in her notes, and then in her head. She does not transform the material; she files it "as is". She willingly reproduces the material on demand, as on an exam; but she feels betrayed if the teacher asks her to "apply" it or to produce materials on her own. (p. 42)

However, during my observation, rather than the "subjective" knowing that follows "received" in Belenky et al.'s (1986) continuum of ways of knowing, Thushara showed signs of the kind of knowing the former call "procedural": "Unlike many of the [subjective knowers], [procedural knowers] retain some trust in authority. The presence of fairly benign authorities may be critical to the development of the voice

of reason" (p. 90). I believe that one of her tutors, Kamala, Prema, some other CEPD colleagues, and I were for Thushara such "benign authorities." But since it was very hard to hear Thushara's voice of reason, I believe Belenky et al.'s (1986) continuum holds true, and that Thushara was discovering the limits of received knowing:

The women ... bring this era to an end with critiques of their tendency to subordinate their own perceptions and judgements to those of others, of their selflessness, of their voicelessness. (p. 51)

Thus at the end of my study, I believe Thushara's voice reflected the "emergence of subjective knowing" where "there is still the conviction that there are right answers" (p. 54). Belenky et al. (1986) found that "almost half [of the 135 women interviewed] were predominantly subjectivist in their thinking" (p. 55). Thushara's experience may thus be quite similar to a significant number of her female colleagues. In its contribution to the aims of my study, Thushara's narrative thus helped me realize the need to encourage teachers' voices, to support their efforts to change and adapt, and to help them learn when to question authority and when to trust their own reasoning.

# TEACHING MATHEMATICS IN THE SPIRIT OF EDUCATION REFORM: PERSPECTIVES FROM THE UNITED STATES AND NAMIBIA

Thea K. Dunn  
University of Wisconsin-River Falls  
thea.k.dunn@uwrf.edu

The outcome of an ongoing, multi-year initiative to enhance mathematics teaching and learning, this transnational study examines the experiences of elementary teachers in the United States and Namibia learning to teach in the spirit of national reform efforts. Qualitative methods were employed to gather and analyze the data. The analysis suggests that several factors played a role in learning to teach mathematics as envisioned within education reform documents: mentoring, reflection, technology tools, reform-based curriculum materials, and collaboration within a mutually supportive environment. The teachers' conceptualizations of an effective mathematics teacher, their conceptual knowledge of elementary mathematics content, and the nature of the learning environment facilitated or impeded this process. Because this study provides some insight into the complexities of implementing mathematics teaching practices as envisaged by education reform agendas, it has the potential to inform the structure and content of professional development workshops and elementary mathematics methods courses.

## Introduction

After a protracted armed struggle for liberation from the colonial apartheid government of South Africa, Namibia became an independent nation in 1990. Although the apartheid forces were defeated, the legacies of the illegal and repressive regime, including an educational system shaped by divisive and dehumanising imperialist policies, remained. As they abolished the discriminatory and inequitable Bantu educational system and developed a new praxis, the Namibian government mandated reforms based upon the goals of access, equity, quality, and democracy (Ministry of Education and Culture [MEC], 1993). The transformed educational system is modelled along democratic, empowering, and reconstructive lines. As such, it rejects the authoritarian, teacher-centre Bantu system, emphasises student-centred learning, uses English rather than Afrikaans as the medium of instruction, and takes into account students' prior experiences and their intellectual, emotional, social, physical, aesthetic, moral and spiritual development. The redesigned school curriculum is structured upon a constructivist view of knowledge, learning competencies in content areas, and developing a reflective attitude and creative, analytical and critical thinking (National Institute for Educational Development [NIED], 1998).

In the United States, mathematics education reforms provide vision and direction for school mathematics (Conference Board of the Mathematical Sciences [CBMS], 2001; Mathematical Sciences Education Board [MSEB] & National Research Coun-

cil [NRC], 1990; National Council of Teachers of Mathematics [NCTM], 2000). A prominent reform-oriented view advocates teaching mathematics in such a way that all students develop "mathematical power" (NCTM, 1989, 2000). Mathematical power includes both ability (to conjecture, reason logically, solve nonroutine problems, and communicate about mathematics) and attitude (self-confidence and a disposition to question, explore, and engage in significant mathematical problems). This goal requires that teachers use knowledge of how students construct conceptualizations of mathematical concepts to select and use materials, develop multiple teaching strategies and instructional activities, design and utilize authentic assessment strategies, and create learning environments in which all students learn mathematics meaningfully. Implementation of these reforms regarding mathematics curriculum and instructional practice requires that teachers and students engage in problem solving, reasoning, communicating, and making mathematical connections.

Although they arose from very different circumstances, in calling for high quality mathematics instruction for all learners, the reform movements of both Namibia and the United States make clear a commitment to equity. In addition to supporting democratic reforms in teaching and teacher education, the emphasis on a constructivist approach to mathematics teaching and learning provides a vision of mathematics education that differs markedly from present practice in many U.S. and Namibian classrooms. To further the implementation of the education reform agendas of both nations, teachers must develop a new perspective on mathematics teaching and learning. This includes possessing a deep understanding of the mathematics they teach and using instructional strategies that promote the active engagement of learners and develop both conceptual and procedural knowledge. The study reported here is part of a larger study designed to explore the process of learning to teach in the spirit of education reform among a small group of elementary teachers in the United States and Namibia. The inquiry was guided by the question, "What strategies are useful in preparing teachers for mathematics teaching as envisioned within education reform documents?"

### **Theoretical Framework**

Elementary teachers' weak mathematical knowledge (Ball, 1990, 1991; Thompson, 1992) and relatively narrow conceptions of mathematics pedagogy (Brown, Cooney, & Jones, 1990; Lampert & Ball, 1998) have been well documented. In an effort to determine whether certain strategies are useful in preparing elementary teachers for reform-based teaching, this study was guided by the intersection of research, theory, and practice in the areas of reflective practice and technology tools.

### **Reflective Practice**

A goal of many teacher education programs is to develop the teacher into a reflective practitioner, "who perceives every experience as an opportunity for growth,

change, and development of understanding” (Hutchinson & Allen, 1997, p. 226). The *Principles and Standards for School Mathematics* (NCTM, 2000) and the *Subject Area Curriculum for Educational Theory and Practice* (MEC, 1992) highlight the importance of teachers engaging in reflective practice. As defined by Dewey (1933), reflective practice may be viewed as a dynamic process that requires an action outcome. The process of facilitating critical reflection draws upon the notion that teachers are expected to become more self-consciously reflective about their actions (Schon, 1983). However, as Risko, Roskos & Vukelich (1999) insist, “prospective teachers need explicit guidance in reflection so as to advance their natural tendencies beyond mindless ritual towards a critical stance on the pedagogic understandings and actions” (p. 7). During the course of teacher preparation programs, myths and stereotypes regarding diverse student populations may be woven and reinforced time and time again (Flores, Tefft Cousin, Diaz, 1991). Without structured reflection, pre-service teachers’ misconceptions may be reinforced rather than challenged (O’Grady, 1998). While teacher behavior may be influenced by prior educational experiences, experience is educative only with time for reflection (Richardson, 1990). As teachers become reflective in their teaching experiences and classroom practices, they develop a critical perspective on education and reconceptualize their image of teaching and learning (Howard, 1995). In an attempt to address the gap in the research on reflection in mathematics teaching (Ball, 1996), this study examines elementary teachers engaging in reflective practice on reform-based mathematics teaching.

### Technology Tools

Research on the appropriate use of technology reveals that technology tools can enhance mathematical knowledge and conceptual understandings (Grouws & Cebulla, 1999; Wattenberg & Zia, 2000). Because they enable users to visualize and experience mathematics, engage in real-world problem solving, and generate representations of their own learning, technology tools are important resources for teaching and learning mathematics (International Society for Technology in Education, 2000). According to the National Council of Teachers of Mathematics’ *Technology Principle*: “Mathematics Instructional programs should use technology to help all students understand mathematics and should prepare them to use mathematics in an increasingly technological world.” (NCTM, 2000, p. 40). This suggests that teachers should be provided with adequate preparation and support to implement technology tools in their classrooms. Teachers should be provided with ongoing mentoring and should have time and support to familiarize themselves with software and content to incorporate technology into their lesson plans (President’s Committee of Advisors on Science and Technology [PCAST], 1997). Technology tools to enhance teaching and learning should be an integral component of teacher education programs (Knapp & Glenn, 1996). Teachers should be provided with ongoing mentoring, time, and support to learn and to incorporate technology into their lesson plans (PCAST, 1997). An integral component of

professional development should be to model for teachers the ways in which technology tools can be utilized to enhance mathematics teaching and learning (Barron & Goldman, 1994). The current study draws inspiration from these earlier studies and seeks to draw together the findings from these works to inform practice and to form a new perspective from which to view elementary teachers learning to teach in the spirit of education reforms.

### Methods and Data Sources

The methodological underpinning of this study is derived largely from orientations to research that draw attention to the importance of detailed qualitative fieldwork and the observation and analysis of participants in contexts (Goetz & LeCompte, 1984); in this case, educational settings in the United States and Namibia.

#### Participants, Site, and Context

Participants included four elementary teachers in the United States and four in Namibia who had voluntarily enrolled in professional development workshops designed and facilitated by the researcher. Two of the Namibian teachers were in their second year of teaching and had completed the Basic Education Teachers' Diploma (BETD). Introduced in 1993, the three-year post grade twelve BETD was designed to support the effective teaching of the post-independence primary school curriculum. Two other Namibian participants were veteran teachers with five or more years of teaching experience and secondary school educations supplemented by post-independence in-service training courses designed to enhance the education of under-qualified in-service teachers. The U.S. participants included two novice teachers with degrees in elementary education. Each was in their second year of teaching in a public elementary school. Two other U.S. teachers who participated in the study were veteran teachers with five or more years of teaching experience.

In an attempt to make teacher preparation congruent with reform documents and reflect a vision of mathematics teaching and learning as described in education reform documents, the workshops are designed to model a learning environment based on constructivist mathematics teaching and learning and attention to issues of access and equity. A fundamental goal of these workshops was to prepare elementary teachers to teach mathematics in the spirit of education reforms. The teachers met in the workshops for one week, then returned to their respective schools. The workshops were designed to challenge the teachers' views about teaching mathematics and to assist them in aligning their teaching with educational reform efforts. During the workshops, the researcher provided a mentoring component and modeled inquiry-based, student-centered, collaborative learning. The participants explored the ways in which reflective practice (journals of reflections), technology tools (*KidPix*, *TesselMania*, *Geometer's Sketchpad*, and *Tabletop Jr.*) and reform-based curriculum materials (*Investigations*, *Everyday Math*, and *Math Trailblazers*) could enhance mathematics teaching and learning.

### **Data Collection and Analysis**

Data collection and analysis took place simultaneously over a two-year period, was grounded in a symbolic interactionist framework (Blumer, 1969), and guided by the constant comparative method of data analysis (Glaser & Strauss, 1967). Consistent with the qualitative research methodology of the study, data were triangulated via multiple sources of evidence, including: (1) participant observations, audiotaping, and field notes of the workshops and the teachers' mathematics lessons in their own classes; (2) three semi-structured, open-ended interviews (Spradley, 1979) with each teacher before, during, and after the workshops; and, (3) collection of the teachers' journals of reflections, lesson plans, and samples of student work. Major themes were developed using thematic analytic strategies (Spradley, 1979). Findings were shared, discussed, and compared by the researcher and the teachers. In order to provide a measure of external validity (Goetz & LeCompte, 1994), the researcher reviewed transcripts and analyses with the participants and allowed them to react to analyses and clarify and elaborate on their responses. This process also enabled the teachers to reflect upon what transpired in their classes when they attempted to align their mathematics teaching with education reforms.

### **Results and Conclusions**

Three major themes emerged from the data analysis. While informative, these present a picture that is general in nature. In order to provide some insights into the totality of an individual teacher's experience, a profile, in the form of an in-depth case study, was compiled for each teacher. These profiles examine the themes in the context of the teachers' own experiences. Segments of the interviews, reflective journal entries, and field notes of observations illustrate that the teachers' conceptualizations of an effective mathematics teacher, their conceptual knowledge of elementary mathematics content, and the nature of the learning environment influenced the types of teaching that emerged among the teachers. Perhaps because reform agendas in the United States and Namibia promote similar views of education, significant differences between the teachers in the United States and the teachers in Namibia did not emerge.

### **Conceptualization of an Effective Mathematics Teacher**

The findings from the present study suggest that one challenge to facilitating teaching in the spirit of education reforms is the teachers' resiliency toward (Lampert & Ball, 1998) and their tendency to rely upon traditional methods of teaching. This appears to be related to an image of an effective mathematics teacher held by the teachers. As they engaged in inquiry-based, student-centered teaching, there was evidence of change with regard to the teachers' conceptualizations of an effective mathematics teacher. Excerpts from the case studies of Amy and Erna suggest a move away from a conception of an effective mathematics teacher as a transmitter to one of a facilitator.

### **The Case of Amy**

At the time of the study, Amy was a first-grade teacher with two years of teaching experience in a U.S. public school. During her initial interview she described an effective mathematics teacher as “someone who can get through all the material the students need to know and give them the skills they will need.” At the onset of the workshop, Amy declared, “an important part of teaching math is showing the children the best way to solve problems.” Although she adhered to these definitions throughout the workshop, observations of her post-workshop teaching revealed that she began to supplement her textbook lessons with several of the student-centered explorations from the *Investigations* curriculum. After successfully teaching several lessons from the *Investigations* curriculum unit on measuring, *Bigger, Taller, Heavier, Smaller*, Amy reflected, “I do see how I *was* more of a guide here. The lessons were so open that the children had to discover the math themselves. My part in it was different than just telling them to do it this way.”

### **The Case of Erna**

A fourth grade novice teacher in a primary school in Namibia, Erna was exposed to reform-based curriculum theory and practice during her Basic Education Teachers' Diploma coursework. Nevertheless, during her initial interview, she identified an effective mathematics teacher as “a person of authority.” Follow-up questions suggest that Erna's conceptualization of an effective mathematics teacher was rooted in her prior educational experiences in authoritarian, teacher-centered classrooms. Observations of workshop sessions demonstrated Erna's engagement and participation in collaborative learning groups and discussions of the role of the teacher as envisaged by reform documents. During her final interview, she expressed one of the most widely noted insights by the teachers: the recognition that “what sense is it hurrying through the content if the learners are not understanding the concepts?” Referring to a discussion that took place during one of the workshop sessions, Erna observed, “It is important for me to remember that I am not the only one with the answers.”

### **Conceptual Knowledge of Elementary Mathematics Content**

It was during the interviews that the teachers' weak conceptual understandings were first revealed. Post-workshop classroom observations confirmed a gap in the teachers' mathematical knowledge as they attempted to think mathematically in a new setting (Crawford, 1992). The data suggest that the teachers' attempts to articulate mathematically sound explanations for the concepts underlying the definitions and make connections between the concepts were undercut by their lack of sufficient content knowledge. Selections from the case studies of Selma and Amber reveal that the teachers' weak conceptual knowledge hindered their ability to engage in reform-based mathematics teaching.

### **The Case of Selma**

At the time of this study, Selma was a third grade teacher in her second year of teaching in a Namibian public school. She had completed the three-year Basic Education Teachers' Diploma program and was eager to learn how to implement reform-based teaching practices in her own classroom. In her second interview, Selma acknowledged her weak mathematical content knowledge. For example, after working with the curriculum materials and the technology tools, she declared, "Honestly, before this workshop, I didn't even know what a trapezoid was or that there were meanings behind the numbers and connections to real things." During her final interview, Selma indicated that she found the collaboration and mentoring especially helpful in developing her mathematical understandings, "We were never left alone to struggle through the problems. There was always someone there to show us another way of looking at the problem." After she returned to her classroom, Selma began to let the students work collaboratively on several of the lessons she explored during the workshop. In a post-workshop journal entry, she reflected, "Teaching this way is more interesting. In fact, I am learning along with the class."

### **The Case of Katie**

Although she had five years of teaching experience in a fourth grade classroom, Katie admitted in a reflective journal entry, "You know, I really don't like math. I know this stems from my own bad experiences. But, I am determined to teach math better than I was taught it." Throughout the workshop, Katie embraced the notion of teaching mathematics for understanding, including the use of technology tools to support the development of conceptual knowledge. After returning to the classroom, Katie struggled with her own weak conceptual understandings. During one observation, she began a conceptually-focused lesson on building understanding of multiplication and division, became confused by a student's question, and quickly reverted to a procedural explanation. Katie reflected on this lesson in her journal, "Today I had an awakening. I was trying to explain a problem and then I realized that I didn't understand it myself so I couldn't explain the WHYS. This experience has taught me to make sure that I understand what I am going to teach."

### **Nature of the Learning Environment**

The workshops provided the teachers with opportunities to experience as students reform-based teaching strategies prior to their utilizing them in their own classrooms (Borasi, 1990). However, the data revealed a conflict between reform-based teaching and the learning environments to which the teachers returned. It appears that, once back in their own learning environments, the lack of professional support, including collaboration and mentoring, prompted several teachers to consider a return to traditional methods. Segments from the case studies of Mary and Amber illustrate how the nature of the learning environment influenced the teachers' abilities to implement reform-based teaching.

### **The Case of Mary**

At the time of this study, Mary was an experienced third grade teacher in a Namibian primary school. She had supplemented her secondary school education with several training courses. Mary was an active workshop participant who eagerly embraced the reform-based curriculum materials and acquired competency with the technology tools. During her final interview, Mary expressed a belief that, despite the traditional culture of her school, participating in the workshop and returning to her classroom with a variety of reform-based lessons and instructional strategies would enable her to teach mathematics in the spirit of educational reform documents. However, a post-workshop reflective journal entry suggests that the nature of the learning environment to which Mary returned might have hindered her ability to implement reform-based teaching practices, "I am striving to make my classroom as modeled in the workshop. I did see a new culture. Yet, I am the only one here doing these things?"

### **The Case of Amber**

When this study took place, Amber was in her second year as a teacher in a multi-grade, fifth/sixth grade classroom in a U.S. public school. Throughout the study, she enthusiastically embraced the notion of increased conceptual experiences for mathematics learners. During her second interview, Amber mentioned several ideas that she would implement in her own classroom, "Because I think students learn best through hands-on activities, I plan to bring manipulatives and collaborative group work into all my math lessons." While Amber remained enthusiastic about inquiry-based lessons, the reality of implementing this approach in her classroom of thirty students was overpowering. The culture of the school had made the students comfortable with teacher-centered, procedurally-focused lessons with an emphasis on drill and practice. During her final interview, Amber said, "I am really excited about all this but the kids aren't used to it, you know? I can see that it takes a lot to make it all work, the computers, writing about math, and so on."

The present study suggests areas for continued research that will foster an understanding of how teachers construct an image of mathematics teaching as portrayed in reform documents. This study revealed that mentoring, reflection, technology tools, reform-based curriculum materials, and collaboration within a mutually supportive environment played a role in facilitating mathematics teaching as envisioned within education reform documents. A related study, underway for the past year, is examining the impact of video episodes of reform-based teaching on the learning-to-teach process among preservice elementary teachers enrolled in a field-based methods course (Dunn, 2002). One challenge is to provide for sustained and adequate mentorship opportunities that assist teachers in developing competencies in reform-based mathematics teaching. The implications highlighted by the present study, including preparing teachers to incorporate teaching strategies that address educational reforms

support efforts to implement reform-based practices in teacher preparation and have the potential to inform the structure and content of inservice and preservice programs. The next critical step will be to develop strategies to help all teachers engage in and sustain reform-based mathematics teaching.

## WHAT DO ELEMENTARY TEACHERS LEARN FROM REFORM MATHEMATICS TEXTBOOKS?

Theresa J. Grant, Kate Kline, & Marcia Weinhold  
Western Michigan University  
terry.grant@wmich.edu

This study was undertaken to better understand what happens when teachers implement a reform curriculum designed specifically to communicate mathematics content and pedagogy to teachers. More specifically, the study focuses on what aspects of the curriculum materials teachers consider as they decide what they will enact in the classroom. Information was gathered to determine the extent to which teachers were understanding the main mathematical content of their first unit on number, the kinds of thinking that students were intended to develop, and how useful the supporting materials embedded in the curriculum were in helping them enact the curriculum. The findings in this study about what teachers learn from this supporting information should be of interest to researchers, curriculum developers, and professional development providers as they consider ways to support teachers' implementation of reform curricula.

Research in the last two decades on teachers' use of mathematics textbooks necessarily utilized traditional textbooks as the teachers' main resource. Findings from these studies indicate that teachers often make major alterations to the textbook lessons resulting in an "enacted" curriculum that looks very different from the intended curriculum (Ball, 1988; Grant & Kline, 2002; Remillard, 2000). In addition, the teachers struggled to create a coherent and effective "enacted" curriculum. Therefore, suggestions were made to include in current reform textbooks more information to help teachers learn and to support their creation of an "enacted" curriculum.

In considering what types of information might be useful to teachers, Davenport and Sassi (1995) made available a collection of approximately 600 resources (articles, videotapes, curriculum materials, etc.) to a group of elementary teachers as they worked to think differently about mathematics teaching and learning. The teachers were allowed to choose which resources they wanted to explore and submit reflective writings on the usefulness of these resources. The majority of teachers chose resources that used a narrative structure to provide concrete images of classroom discussions, student thinking, and common misconceptions. Clearly narratives, as an external resource, had a powerful impact on teacher learning. However, it remains to be seen what impact this type of information could have on teacher learning if imbedded within curriculum materials and how this type of information might effect the enacted curriculum teachers create. This study investigates this issue by considering the following question: what about reform curriculum materials do teachers consider and how does this material impact their thinking?

## Methodology

### Context

This study takes place in the context of a three year funded project designed to support more than 325 teachers and administrators in six local school districts (urban, suburban, rural, public, and private) as they work to improve mathematics teaching and learning. These districts all adopted one of the National Science Foundation-funded reform curricula, *Investigations in Number, Data and Space* (henceforth called *Investigations*), which focuses on reasoning and problem solving where students are encouraged to make sense of the mathematics they are learning and to use procedures that they understand, rather than those they may have memorized but may not fully understand. One of the goals of this curriculum is to communicate mathematics content and pedagogy to teachers by including information, often in narrative form, describing the importance of particular content, describing various strategies students may use and why they work, discussing connections among topics, and providing sample conversations a teacher may have with a student or group of students on a particular mathematical idea. The curriculum is structured into separate modules focusing on particular mathematical topics. There are 6 - 11 modules at each grade level with at least two at the lower elementary level and at least three modules at the upper elementary level focusing on number.

### Data

All 329 K-5 teachers in the 6 districts in the project were sent a survey asking them to analyze one module at their grade level. One hundred and twenty-three teachers completed and returned the surveys, representing 5 of the 6 districts in the project in grades K, 1, 3 and 5, and all 6 districts in grades 2 & 4. These teachers represented a range of years teaching in general as well as teaching *Investigations*, although the majority of teachers were less experienced with the curriculum. Sixty-one percent of the teachers who returned surveys had only 1-2 years experience using *Investigations*, while the others had 3 or more years experience, and often more than 5. The first module on number at each grade level was chosen for the analysis, because they involved a topic every teacher would certainly deem important and there was a guarantee that every teacher would actually teach the modules since they appeared in the beginning of the school year.

The intent of the survey was to gather information on what the teachers were considering in each particular module. One section of the survey focused on what teachers thought of the information provided to them in the curriculum materials, referred to as Teacher Notes (TNs) and Dialogue Boxes (DBs). The TNs provide information typically on the mathematics content and on the ways in which children think about the content. The DBs provide examples of classroom discussions around the content. Each survey included a list of all the TNs and DBs in the unit, the number of which

ranged from 13 in grade 3 to 30 in grade 1, and asked that teachers rate each item as to its usefulness, on a scale of 1 to 4 if they had read the item; otherwise, they were to indicate that the item was “never read.” The teachers were then asked to choose, and provide a rationale for their choice, the TN/DB that they found most helpful and the one they found least helpful. A second section of the survey asked the teachers to reflect on the unit as a whole and describe the mathematics content the students learn, the specific strategies or ways of thinking about number that were developed in the unit, and their overall impressions of the unit.

Approximately a year later, a short follow-up survey was administered asking teachers to assess the helpfulness of a variety of different factors in their efforts to implement the *Investigations* curriculum. They had to rank, from 1 to 4, the helpfulness of: reading the information provided in the curriculum materials; attending various forms of professional development; observing their students during implementation; and talking with other teachers.

## Analysis

### TNs and DBs

The teachers' ranks for TNs and DBs from 1 to 4 were segregated into ranks of 1 and 2 (generally not useful) and ranks of 3 and 4 (generally useful). The averages for teachers overall as well as the averages by grade level were analyzed for any patterns that would indicate the types of TNs or DBs teachers were choosing as useful or not. Explanations for the teachers' choices of most or least helpful TN or DB were coded into 6 general categories—mathematical content understanding, pedagogical understanding, understanding student thinking, management, time, and general comments. Mathematical content understanding referred to explanations that expressed an enhanced understanding of the teacher's own mathematics. Pedagogical understanding referred to explanations that expressed a better grasp of how to teach the material at hand. Understanding student thinking was used when teachers explained that the TN or DB helped them interpret different types of student responses and what those indicate about the students' understanding. Management and time were used when teachers explained that a TN or DB helped them with management, such as organizing materials, assigning partners, etc., or when they helped them structure the time spent on any given activity in the lesson. Finally, explanations were coded as general when they were not specific to a particular TN or DB. For example, some teachers simply stated that they use all of the TNs and DBs or that they liked this feature in the curriculum in general.

Within these categories, responses were also coded as to whether the teachers had a more critical or negative impression of the TNs or DBs or whether they simply disagreed with the information given in them. For example, a response that was coded as negative for pedagogical understanding was “This shows students thinking aloud, but

it doesn't give any help for students who are stuck." Another example of a response that was coded as negative was "I was still confused about what I was supposed to get the students to understand." Finally, these explanations were analyzed by looking for trends among the teachers overall as well as by looking for trends among less experienced teachers (1-2 years experience with *Investigations*) and more experienced teachers (3 or more years experience).

### **Description of Mathematical Emphasis of Unit and Student Strategies**

The teachers' descriptions of the mathematical intent of the unit and the strategies students learned after completing the unit were also coded. The teachers' descriptions of the mathematics were coded to represent the extent to which they captured the mathematical emphasis of the unit. A 4 represented a detailed description of content or a well-developed characterization of big ideas; a 3 represented a description of some big ideas but may have other less developed descriptions included, or a good list; a 2 represented lists with little description, often including less important ideas; a 1 represented no identification or description of big ideas; and a 0 was used for no answer or negative comments.

These descriptions were also analyzed by looking for trends among the teachers overall as well as by looking for trends among less experienced teachers (1-2 years experience with *Investigations*) and more experienced teachers (3 or more years experience).

The descriptions of student strategies were coded for their level of persuasiveness. A response was coded as "persuasive" if it contained a detailed description of the idea or used names of strategies that were well understood and "not persuasive" if it seemed to focus narrowly on more insignificant mathematical ideas or strategies or missed important ideas. Some examples of descriptions that were "not persuasive" were "It utilizes children's many ways of looking at the world and making sense of it" and "I think the emphasis on the idea of more than one way to solve/record results from activities an important concept for children to know." The first example does not describe a strategy per se and the second example speaks about the teacher's objectives rather than strategies.

## **Results and Discussion**

### **What Materials Were Considered?**

In general, the teachers read the majority of TNs and DBs in their unit and rated them as being useful in implementing *Investigations*. See Table 1. The largest proportion of unread TNs and DBs occurred in kindergarten. This may be due to the fact that these units were published last so that many of the teachers had not been able to read all of the support materials in that particular unit. The teachers were also very willing to rate some TNs and DBs as not useful (those rated 1 & 2). There was no pattern in

the ratings they made, except that many rated TNs dealing with management issues, such as storing manipulatives, etc., as not useful (or perhaps not necessary).

This overall impression of the TNs and DBs being useful is further supported by the teachers' reasons for their choice of most helpful TN or DB. As Table 2 illustrates, the majority of teachers' reasons dealt mainly with the substantive issues of understanding how children think and orchestrating classroom discourse. In particular, the teachers appreciated seeing sample student work and commented on the usefulness of

**Table 1.** Usefulness of TNs and DBs

| <b>Teacher Notes (TNs)</b>  |          |              |               |              |               |              |

**Table 2.** Reasons for Choosing TN/DB as "Most Helpful"

|  | <b>K</b> | <b>1</b> | <b>2</b> | <b>3</b> | <b>4</b> | <b>5</b> |
|--|----------|----------|----------|----------|----------|----------|
| helped understand the mathematics content better                 | 14%      | 6%       | 13%      | 16%      | 42%      | 30%      |
| helped understand how children think or what they might do       | 43%      | 25%      | 58%      | 42%      | 19%      | 20%      |
| helped make pedagogical decisions related to classroom discourse | 36%      | 56%      | 23%      | 37%      | 31%      | 40%      |
| helped with general management                                   | 7%       | 14%      | 6%       | 5%       | 8%       | 10%      |

having examples of how to handle incorrect answers. Although many teachers felt that the supporting materials also helped them understand mathematics content better, this was more pronounced in the upper grades.

Finally, there did not seem to be any preference for TNs versus DBs. Overall, TNs were chosen as most or least helpful about 70% of the time. This is in keeping with the general proportion of TNs to DBs in each of the units in that typically 67% of the supporting materials in each unit are TNs. This was the case at all grade levels for most helpful, and all but one grade level for least helpful. Grade 3 teachers chose DBs as being least helpful at a higher rate than TNs. In this case the results are understandable as one DB was from an excursion lesson (which is skipped by most teachers) and the other was the first DB in the unit, which is purposefully simplistic.

These results were also analyzed according to years of experience with the curriculum. One might assume that more experienced teachers would make different choices than less experienced teachers in identifying supporting materials that were most helpful or least helpful. For example, more experienced teachers who have had more time to understand the content and student thinking might rely more on the DBs to help them facilitate richer discussions. However, there was no difference in the choices made by less experienced versus more experienced teachers. It could be the case that the more experienced teachers identified what had impacted them the most in all their years of teaching rather than what impacted them in their most recent year of teaching. This would basically remove the effect that experience might have on the teachers' choices.

### **How Did the Materials Impact the Teachers?**

#### **Describing Mathematical Emphases of the Units**

In general, the majority of teachers (69%) were able to identify and describe the important mathematical emphases of the units at their grade level. Their descriptions referred to such topics as recognizing and using landmark numbers to navigate the number system, developing number sense, and understanding the meaning of the operations. Some teachers, particularly at the primary level, had difficulty distinguishing between actual content goals versus such process goals as problem solving, communicating, and representing. Although they were asked to describe the mathematics content they thought students would learn, close to 28% of the K-2 teachers' responses dealt with process goals. Grade two teachers spoke more about processes than any other grade. In addition, kindergarten teachers often discussed the notion of "representing quantities with pictures, numerals or words." While this is an important process goal in the curriculum, it can be problematic if teachers are focusing on this without thinking about the mathematics content children are using and exploring by doing the representations. This may suggest that it is necessary to make a stronger distinction between content and process goals in curriculum materials.

The results of analyzing teachers' descriptions of the mathematical intent of the units according to their levels of experience with the curriculum are shown in Table 3. Overall the more experienced teachers were better able to describe the mathematical emphases of their units. This suggests that there is an effect of experience on understanding of content, or at least the ability to describe that content well. As Table 3 shows, this result holds true for all grade levels except kindergarten. In light of the fact that there is only one kindergarten teacher with 3 or more years experience, this exception is not significant. Any additional analysis of grade level variations, like the fact that more experienced second and fifth grade teachers seemed to show particular strength in describing the mathematical emphases in their units, does not seem reasonable given the relatively small numbers of teachers at any particular grade level.

Finally, there were four teachers (two more experienced, two less experienced) who commented negatively about the mathematics content in some of the units. Their comments focused on two issues: some believed that the content of the first number module was mainly review; others felt that there was not enough practice with memorizing basic facts. Both issues speak to a major philosophical difference between reform-based curricula and traditional curricula – the reform-based curricula are purposefully designed to provide students with more time developing both conceptual and procedural ideas before encouraging students to work towards fluency.

**Table 3.** Quality of Description of Mathematical Emphases of Units

| <b>Teachers with 1-2 Years Experience with Investigations</b>       |      |                 |                 |                 |                 |                 |     |

|   | K    | 1 <sup>st</sup> | 2 <sup>nd</sup> | 3 <sup>rd</sup> | 4 <sup>th</sup> | 5 <sup>th</sup> | K-5 |
| Ranked 3 or 4   | 77%  | 50%             | 64%             | 53%             | 77%             | 50%             | 64% |
| Ranked 1 or 2   | 11%  | 50%             | 28%             | 47%             | 23%             | 25%             | 33% |
| Negative  | 0%   | 0%              | 7%              | 0%              | 0%              | 25%             | 3%  |
| Total # of Teachers   | 8    | 12              | 14              | 15              | 13              | 4               | 66  |
| <b>Teachers with 3 or More Years Experience with Investigations</b> |      |                 |                 |                 |                 |                 |     |
| Ranked 3 or 4   | 0%   | 60%             | 92%             | 67%             | 77%             | 100%            | 78% |
| Ranked 1 or 2   | 100% | 40%             | 8%              | 33%             | 0%              | 0%              | 17% |

So, for example, in *Investigations* students are expected to develop fluency in single digit addition by the end of second grade only after spending two years working on addition. They memorize some facts and developing efficient retrieval strategies for those facts they do not have memorized throughout this time. This is contrasted with the practice of drilling addition facts in first and second grade before students have had time to develop their own strategies. These concerns are fairly typical for teachers first encountering a reform-based curriculum. The fact that there were not more negative comments by the less experienced teachers is most likely due to two factors: teachers with these negative opinions about the units may have been less likely to fill out the survey, and all teachers sent this survey were part of a long-term professional development project which addressed these concerns.

### **Description of Student Strategies**

When asked to describe specific strategies or ways of thinking about number that their students developed during their unit, the teachers were generally able to identify important strategies. Overall, 82% of the teachers who responded to the question were able to provide persuasive descriptions of these strategies. For example, a persuasive response related to using relationships among problems was “using landmark factor pairs, like  $2 \times 25$  and  $2 \times 50$ , and building on those to pairs like  $40 \times 25$ ,  $40 \times 250$ ,  $20 \times 50$  and  $20 \times 500$ .” Those responses that were not persuasive often focused on content issues rather than student strategies.

### **Other Factors Impacting Teachers Learning**

One may argue that it is difficult to tease out which factors are really impacting teachers’ learning as they implement a new curriculum and specify the impact of the curriculum materials themselves. For example, there is no question that teachers also learn from the professional development in which they participate as well as from working with their students as they experience the activities in the curriculum. In a follow-up survey on which teachers were asked to rank (on a scale of 1-4) the impact of some of these factors on their implementation efforts, reading the curriculum materials (average rank 3.3) was second only to talking to other teachers (average rank 3.5). This suggests the teachers certainly value the supporting curriculum materials and find them to be a critical component in their efforts to implement the curriculum. Having said this, it is important to point out that the professional development experienced by these teachers did make deliberate use of these supporting materials on occasion, and thus may have influenced the value teachers placed on them.

### **Conclusion**

The supporting materials in the *Investigations* curriculum clearly had a significant impact on the teachers, demonstrating that it is possible to produce curriculum materials that help teachers learn at the same time as supporting them in teaching. The

teachers' choices of most helpful TNs and DBs, and their rationales for those choices, focused on the issues the curriculum developers intended – the mathematics content, ways of thinking students might display, or pedagogical support – rather than less substantive issues of general management and time. In addition, the fact that more experienced teachers were better able to describe the mathematics content focus of their units suggests that teachers continue to learn and deepen their understanding the more they use the curriculum materials. However, many teachers' propensity to blend content and process goals suggests that more discussion is required in the curriculum materials themselves to help teachers distinguish among these ideas. Finally, it would be useful to conduct a similar study with teachers who were not part of a long-term professional development project to better assess the impact of professional development on their interpretation of the curriculum in general, and the supporting materials in particular.

## QUESTIONS THAT ENGAGE STUDENTS IN MATHEMATICAL THINKING

Daniel R. Ilaria  
Rutgers University  
Dilariaj@aol.com

Teacher questions are an important part of a student-inquiry classroom. This research examines two different student-centered settings to determine the teacher questions that engaged students in mathematical thinking. It reports on questions asked in both a research setting and a high school classroom. Discursive and retracing questions are defined as asking a student to contribute to an ongoing discourse and consider an old idea, respectively. These questions started strands of student engagement in mathematical thinking. Confirmation, justification, and clarification questions were also asked by both teachers and kept students engaged in mathematical thinking.

Recent reform efforts in mathematics education promote communication as an essential part of the mathematics classroom. Communication makes ideas objects of reflection, discussion, and refinement as part of the process of organizing, consolidating and giving meaning to these ideas (NCTM, 2000). If students are expected to explain their ideas, a question arises about what influence, if any, a teacher's response to those explanations has on student thinking. While a range of pedagogical responses is possible, a key way to facilitate communication and discover student thinking is teacher questions.

If mathematics teachers teach in an environment filled with conversation and where student ideas are valued, then teachers must know what questions engage students in mathematical thinking. While there have been many studies published on teacher questioning, most of them focus on the teacher. Some of this general education literature examines the effectiveness of teaching (Gall & Rhody, 1987) and categorizes teacher questioning (Cotton, 1989; Cunningham, 1987) according to student achievement. Other literature looks at how questioning strategies can involve more students in the learning process by provoking thoughtful responses (Wigle, 1999; Mewborn & Huberty, 1999). While bodies of mathematics education literature examine teacher questioning of students (Maher & Davis, 1990; Maher, Davis & Alston, 1992; Maher & Martino, 1992; Martino & Maher, 1999; Martino & Maher, 1994; Vacc, 1993) and students' learning and understanding of mathematics (Cobb, Wood & Yackel, 1992; Davis & Maher, 1990; Yackel & Cobb, 1996), there has not been an integration of these two research areas. Influenced by the call for communication in student-centered classrooms, the purpose of questioning is to help students explore their ideas during the communication process. Therefore, teachers need guidelines for questions that engage students in mathematical thinking. During a student and teacher conversation, teachers cannot use prepared questions or prescribed strategies. Teacher questions need to be based on the responses received from the student so the

teacher can continue the conversation in order to engage the student in mathematical thinking.

The purpose of this study is to address this imbalance in the literature and inform mathematics education practice by classifying and describing teacher questions that engage students in mathematical thinking within a student-centered setting. The following research questions frame the study: 1) What kinds of questions do mathematics teachers in two different settings ask?; 2) What questions engage students in mathematical thinking?

### **Theoretical Framework**

The call for communication is influenced by research in constructivism and discourse. These two research areas lead to the promotion of classrooms where students take an active role in learning and gain mathematical knowledge through social interaction and experience (Noddings, 1990; von Glasersfeld, 1990). As a result, teacher questions are an important aspect of student engagement in mathematical thinking. Since this study focuses on teacher questions, literature in this area supports the framework for the study.

### **Teacher Questioning and Questions**

Questions are a valuable teaching tool and by far the most used technique of teaching (Clegg, 1987). Questions serve many purposes, such as initiating discussion and reviewing material, but the purpose of the question determines the kind of question asked by the teacher (Cunningham, 1987). Research, from general education classes, on questions provides many classification schemes, which label questions according to a particular cognitive level of student thinking.

Woolfolk (1998) suggests categorizing questions into divergent questions, which have many possible answers, or convergent questions, which have one right answer. Cotton (1989) found the majority of researchers conducted similar dualistic comparisons about questioning and Cunningham (1987) provides a more extensive list of questions for teachers to ask based upon the cognitive level of student responses.

Another view of questions is to categorize them in a hierarchy. The most widely used hierarchy is Bloom's taxonomy, where questions are labeled from simple to complex cognitive objectives (Woolfolk, 1998). Wolf (1987) suggests a different hierarchy, which focuses solely on what he considers challenging questions, from observations in his classroom.

A third view of questions is their role in effective teaching. This more current research shows that communication and questioning are part of a larger equation for effective teaching (Glenn, 2001). Effective teachers tend to ask more process questions, asking for explanations, though the majority of questions were product questions, asking for a single response (Reynolds & Muijs, 1999).

## Questioning in Mathematics

Research regarding questioning in mathematics classrooms also focuses on classification schemes. Hiebert and Wearne (1993) identify four types of questions: recall, describe strategy, generate problem, examine underlying features. Vacc (1993) cites three categories of questions that occur in the classroom; factual, reasoning, and open based on a study by Barnes (as cited in Vacc, 1993) on questioning in classroom instruction. Vacc (1993) concludes that teachers asking factual questions will find out the specific facts their students know, but teachers who ask questions in the open category gain information about their students' cognitions. While the conclusions are helpful, there are no specific questioning guidelines offered or connections to student mathematical thinking.

Additional research examines questioning strategies and how questions can get students to communicate mathematical ideas. Mewborn and Huberty (1999) advocate a question-listen-question strategy in order to encourage discourse. The study reports how teachers, using questions from the NCTM Standards, improved discourse, but does not provide a classification for the questions in the study.

An examination of teacher questioning, by Martino and Maher (1999), explains how the timing of questions can determine a student's understanding of a mathematical idea after students construct their own ideas. In order to build upon student ideas, the research proposes asking students questions that lead them to justifying their ideas. Dann, Pantozzi and Steencken (1995) also examine teacher and student discourse and recommend that teacher's ask questions, which promote student interaction to help extend their ideas and justify their conclusions. Research in this area supports the idea that questions can encourage students to talk about mathematics, but this research does not classify questions, which promote mathematical thinking.

## Research Design

This case study examines two settings in order to provide insight into questions teachers ask and what questions engage students in mathematical thinking.

## Participants and Settings

The first setting for data collection is an urban high school classroom. Thirty-five honors students, comprised of sophomores and juniors, work on calculus problems at individual desks in rows. The teacher being observed is a 30-year veteran of the school system and holds a doctorate in education.

The second setting is a component of a longitudinal study on the development of proof making in students<sup>1</sup>. Eighteen high school students, entering their fourth year, work in groups on an open-ended precalculus mathematics problem in a library of a high school. The students are seated in groups and five teacher/researchers interact with the students. Six students, sitting at the same table (two males and four females), and one teacher/researcher, an experienced professor of mathematics and mathematics education at the university level, have been selected for this study.

### **Data Collection and Analysis**

Eighty-minute videotape observations of the high school classroom sessions and two-hour videotape sessions of the two-week institute, both from a consecutive three-day period, comprise the data for this study. Field notes from both settings account for events beyond the view of the camera and summarize the class activity.

The analysis of the data for this study follows the model provided by Powell, Francisco & Maher (2001). Videotape were digitized onto CDs and each CD was summarized. Repeated viewing of the data allowed for the identification of critical events. A critical event, for this study, is defined as a teacher-student interaction where student mathematical thinking could be followed. The codes emerging from the data are: T(r): Teacher asks a student to consider an old idea; T(d): Teacher asks a student to contribute to the ongoing discourse; T(c): Teacher asks the student to clarify their statements or ideas; T(j): Teacher asks the student to justify their statements or ideas; T(con): Teacher confirms the student and teacher both agree on what has been done or said; and T(f): Teacher follows the student's idea or suggestion. It is possible for one question to receive multiple codes.

### **Results**

The episodes selected demonstrate strands of student engagement in mathematical thinking. The strands presented here show teacher questions, with codes, that were common in both settings.

#### **Summer Institute**

The task the students are working on during the Institute is called Placentieras, developed by Bob Speiser. The first part of the task is to draw a ray from the center of the shell in any direction. Then using polar coordinates as a way to describe the spiral of the shell, the students are to make a table of  $r$  as a function of  $\theta$ . The question for the task is what could be said about  $r$  as a function of  $\theta$ .

#### **Episode 1**

During the morning session, the students make measurements from a picture of the shell and create a table. They talk with each other about how to enter the points from their table into the TI-89 calculators in order to graph a function. Alice interacts with the group throughout the morning session about the where their measurements come from and what the number representing an average means. The students tell her their measurements go from the origin out to the shell, a radius, and the average is the distance traveled along the shell per 90 degrees. The students develop the equation  $r$  equals .039337 times  $\theta$ , where .039337 is a result of their work on determining an average. In this day's afternoon session, Alice returns to the group and questions Victor.

- Alice T(r) If we're saying, you told me the radius, which is the distance out to an point, is equal to that number that you came up with which was .039337
- Victor mm, hmm.
- Alice T(con) Is that right?
- Victor I guess that, that's right for what I said, not right, like correct.
- Alice Oh, no. I'm, I'm just saying.
- Victor Okay.
- Alice T(con) That's what you got and that's what you, that's what you based your spiral on.
- Victor mm, hmm.
- Alice Times theta.
- Victor Right.
- Alice T(c) And theta for this number was in degrees or in radians?
- Victor Degrees.
- Alice T(j) Okay, and so then shouldn't you be able to plug in a number of degrees and get one of your points on the spiral?
- Victor Say that again now.
- Alice T(r, c) If this is an equation that says  $r$  is equal to .039337 times theta, what happens if you plug in a number of degrees? And multiply it by .039337. What should you get?
- Victor A number of radius I guess. The number of the, the radius, right?
- Alice T(con) The, the length of a radius? Is that what you should get?
- Victor Uh huh.
- Alice T(con) But now, isn't that what these things are?[points to values on their spiral]
- Victor Right.
- Alice T(r, j) Well shouldn't she be able to check by going backwards or not?
- Victor shows some frustration with Alice, but agrees to check out if this idea works.
- Alice T(c) What's the degree to get this guy out here[points to the last value on their spiral]?

- Victor Uh, 6.55 radians. Which is about, 6.5 um, 6.5 times 180. 1107.
- Alice T(con) Which is almost your total, wasn't it?
- Victor .0, hmm, .0 what, three.
- Alice 9337.
- Victor No, you don't get the radius. You don't get the radius. Oh dang.
- Alice No, I just.
- Victor You don't get the radius, you get the length.
- Alice T(con,c) What do you get? do you get the length?
- Angela Is it length from like, length like this, that's what you get?
- Victor Yeah.
- Alice T(c) So is that what you are getting?
- Victor That's what I mean. [Referring to the term length rather than radius.]

Alice asks the students to check two more values with their equation.

- Alice T(c) So, so what, what is the thing over here? What is this thing over here? I mean what is it, what's the name of it?
- Victor I don't know. um, (inaudible) of the spiral.
- Angela Some kind of arc length type deal. I don't know.
- Alice T(con) Well arc, arc, whatever. Arc length, Isn't that what you call that?
- Victor Arc something.

### Episode 2

During the last day of working on this task, the students are talking about what they are going to present to the rest of the groups at the summer institute. Alice asks Robert about the two equations the group developed to model the growth of shell. Robert explains how the equations came from the scatter plot the group created, which was made from their table. He also relates the  $x$  and  $y$  values represented on their scatter plot to the values of  $r$  and  $\theta$  measured on the picture of the shell. After finishing his explanation, Alice asks Angela about what Robert said.

- Alice T(d) Angela does that make sense to you at all? or not?
- Angela Sort of. I like get lost with all this stuff. I hate this.
- Alice T(f,c) What, what are the, what is the sort of question that throws you?

- Angela Like, I get like little bits and pieces of what he's explaining, but I don't really get all of it.
- Sherly What don't you understand?
- Angela I don't know.
- Alice T(c) I think I hear (inaudible), she doesn't even know what she's asking. Um what, what are you asking...in this?
- Angela I don't have like a specific question. I just don't like understand the whole, like everything you just explained. Like why that, the whole thing, like what you were saying like why it's like the spiral unraveled or something like that. Like I don't, you explained the points and just trying to follow and just didn't.
- Robert It's kind of hard to explain.

The students ask each other if they understand what Robert explained.

- Alice T(d) Could you, could you try Michelle, to explain. Cause every time one of you explains it, it helps me a little, little more. This is really just as foggy for me, Angela, as it is for you. I am even further away than you, from this stuff, because I don't understand the calculator either. So Michelle could you try it again.
- Michelle Okay, um. Ooh. Alright if you took, let me draw a piece, the spiral, and you picked like certain points, whatever ones they were. Right? Robert?
- Robert Yeah.
- Michelle Okay (laugh), just checking. And like um, you're doing the ninety degree intervals, which is like the  $\pi/2$ , you know what I mean, and like you graph them...Okay, then you're saying that  $r$  would be the radians?

Michelle, with the help of Robert, continues to discuss with Alice the meaning of the values the group measured from the picture of the shell. Alice leaves the discussion after asking the group to show how they used a rubber band to get the lengths in their table.

## High School Classroom<sup>2</sup>

The task the students are working during these observations is to find the area under a curve over a given interval. The teacher provides the students with a function and then calls students to the board to work on a specific part of the task. For episode one, which occurs on the second day of observation, the function given is  $f(x) = 2x^3 + x^2$  over the interval  $[1,3]$ .

**Episode 1**

The students take the derivative of  $f(x) = 2x^3 + x^2$  to get  $f'(x) = 6x^2 + 2x$ . Using the properties of its first and second derivatives, the class draws a graph for  $f(x)$ . The students find the area under the curve using four rectangles. The teacher asks the students to express the area using sigma notation and then assigns various students in the class a number of rectangles to use to calculate the area with a TI-89 calculator. After the class sees the area is approaching 60 as the number of rectangles increases, the teacher asks a student to write the area using limit notation. The student, Cedric,

writes  $\lim_{n \rightarrow \infty} \sum_{i=1}^n \frac{1}{n}$ .

DrG                      Question Keri.

Keri                      Shouldn't it be 2 over  $n$  cause that is how you did everything else.

Cedric                    (inaudible) [calls on a student to answer]

Student                  It should be. That first expression should be  $n$  over 2, which that would be. So that top number which is  $n$  is four. So the number in the denominator is four.

Keri                      But that.

Student                  What?

DrG    T(r, f)          Keri, let us hear your argument again please.

Keri                      Okay, it should be 2 over  $n$ . Because like to get one half, you do two over four. Cause it was like you have four triangles and the area two. Two. So it was two over four, which is one half and you had two over ten which is one fifth. And so on. So wouldn't it be two over  $n$ .

DrG    T(con,d) Any disagreement? Everyone understand that. What'd she say Chuck?

Chuck                    She said that since those four triangles and those were split into two parts. I mean four rectangles. It was two over  $n$ , which was reduced to one half and that's how we got one half.

DrG    T(con)          Is that what you said Keri?

Keri                      Uh, not really.

DrG    T(r,c)          Try it again, Keri. And then we'll back it up and try and have him run it through again.

Keri                      Okay, I don't know how. I'm sure how to explain it. Yeah, You had

okay. You had like two, one to three, three minus one is two. So, you have like two spots and you're doing it for four rectangles. So you did two over four is equal to one half and then you did two over ten is one fifth and so on. So to get it for  $n$ , you get two over  $n$ . I think that's what I said.

DrG T(d,con) So, now you try and say it Chuck.

Chuck Yeah, fine. Uh, Since we're going from one to three, the top part is two. And since there's four rectangles, the bottom part is four.

DrG It's the length of the interval divided by the number of rectangles. [points to the expression written on the board]

The student finishes the expression for the area and writes " $= 60$ ". The class uses the calculator to graph the derivative function and find the area under the curve for the interval  $[1,3]$ . The teacher draws the students' attention to the integral notation on the calculator and introduces paper and pencil integral language using formal, graphical and  $f(x)$  notation. The teacher also explains how to use the TI-89 to calculate the integral of their given derivative function. After this explanation, a new problem to find the area under the curve  $f(x) = 2x^2 + 3x$  over  $[0,1]$  is introduced, and a student is called to the board to calculate the parent function. After calculating the parent function by reversing the power rule for derivatives and finding the area using this method, the teacher asks another student to set up the limit equation, which they will determine for homework.

Marc So just, uh, write the equation. [Student writes  $\lim_{n \rightarrow \infty} \sum_{i=1}^n \frac{1}{n}$ ]

DrG T(r,j) Now, why one over  $n$ ? Awhile ago it was two over  $n$ .

Marc Because the uh, zero to one, not one to three.

DrG Oh, okay.

### Conclusions

The two teachers asked many questions during their interactions with students. However, two questions started student engagement in mathematical thinking, while other questions kept students engaged in mathematical thinking. Retracing and discursive questions, coded T(r) and T(d) respectively, started the strands of student thinking in the episodes selected. The additional questions of clarification, T(c), justification, T(j), and confirmation, T(con), allowed the teachers to keep the student(s) engaged in mathematical thinking.

Both teachers used these questions to engage students in mathematical thinking, but each teacher asked questions for various reasons and purposes. Alice would ask

a question after listening to the students' conversation. Dr. G would ask questions with a goal in mind for the students. His initial questions did not always come from something the students said.

Each teacher utilized retracing questions for different purposes. In episode one of the summer institute observations, Alice questions students about what their measurements mean so they could revisit their own ideas. She continually returns to this idea throughout the day to get the students to clarify their thinking. Finally, in the afternoon session, Victor realizes it is not the radius he is talking about, but rather the arc length of the spiral. Retracing questions allowed Victor to revisit his mathematical thinking about this topic until he clarified the meaning of his measurements.

In the high school setting, the teacher asks retracing questions to emphasize an earlier idea to the entire class. Keri indicates the width of interval should be two over  $n$  and justifies her reasoning. The teacher returns to this idea when a different student is writing the value of the width of the interval for a new problem to emphasize to the class what Keri stated earlier.

Both teachers ask discursive questions to check for other students' understanding of one student's idea. In episode two of the summer institute, Alice asks Angela if she understands what Robert just explained. Since Angela states she does not understand, Alice asks Michelle to see if she understands and can explain Robert's ideas about the group's work. Michelle becomes engaged in mathematical thinking and, with the help of Robert, restates the group's ideas. In the high school classroom, the teacher mimics Alice's objective. He has another student explain what Keri said about the interval width for the rectangles in order to check for understanding of other class members.

Retracing and discursive were the two main types of questions the teachers in both settings used to engage students in mathematical thinking. The transcripts presented also show both teachers using many clarification, justification, and confirmation questions to extend student mathematical thinking. Even though both teachers used these types of questions, Alice asked more clarification and confirmation questions, while Dr. G asked all three kinds of questions. However, the episodes presented only show a very small sample of the overall student-teacher interactions from the two settings over a short observation period. Further quantitative analysis of the entire transcript may provide further insight into the quantity of types of follow-up questions asked by each teacher.

Studies about questioning in the mathematics classroom call upon teachers to ask initial questions that provoke thoughtful responses from students, but to follow initial questions with others that help students clarify, justify and extend their thinking (Dann, Pantozzi & Steencken, 1995; Mewborn & Huberty, 1999). This research shows that teachers can use discursive and retracing questions as initial questions to engage students in mathematical thinking. Teachers can follow these initial questions with clarification, justification, and confirmation questions to extend and continue student mathematical thinking.

### Notes

# A LOOK AT THE “LONG AND SKINNY”: EXAMINING IDEAS ABOUT AREA AND PERIMETER IN THE CONTEXT OF STUDENT PRESENTATIONS

Karen Koellner-Clark  
Georgia State University  
kkoellner@gsu.edu

Roberta Y. Schorr  
Rutgers University  
schorr@rci.rutgers.edu

This paper presents one aspect of a qualitative study that examined one middle school teacher's use of questioning strategies to help students construct, revise, refine and extend their understanding of the relationship between area and perimeter. The teacher was involved in a professional development project where she and several colleagues worked with university researchers to consider ways in which to improve their practice. In this case, they were focusing on the use of questioning techniques to improve the discourse in their classrooms. This paper details one lesson dealing with the relationship between area and perimeter and the questioning strategies used in the context of student presentations. Results indicate that deliberate and careful use of questioning strategies within the context of student presentations clearly aided students in understanding the relationship between perimeter and area. Many misconceptions were identified and discussed through whole class discussion. An additional benefit of reflecting on discourse was that the teachers were able to build new ideas about the ways in which students develop mathematical understanding.

## Introduction and Theoretical Framework

Prompting students to talk about mathematics is an important goal of mathematics education (NCTM 1989, 2000; Cobb, Boufi, McClain, and Whiteneck, 1997). One aspect of this involves providing students with opportunities to discuss their ideas with each other and their peers, defend and justify their thinking, and reflect upon the mathematical thinking of others. Facilitating this type of discourse is no easy task (Ball 1991; NCTM 1991). This study, which is part of a larger project, will examine how one teacher helped to facilitate substantive mathematical discourse in the context of student presentations.

Our analysis will be done in the context of a “models” and “modeling” perspective. In this research both teachers and students were involved in modeling situations where they could continually identify, revise, refine, test and extend their current models of particular situations involving the teaching and learning of mathematics. Briefly, a model can be considered to be a way to describe, explain, construct or manipulate a complex series of experiences. Models help us to organize relevant information and consider meaningful patterns that can be used to interpret or reinterpret hypotheses about given situations or events, generate explanations of how information is related, and make decisions about how and when to use selected cues and information. Models tend to develop in stages and over time (c.f. Schorr and Koellner-Clark, in press), and early conceptualizations may be quite different from later iterations.

Our hypothesis was that student presentations, if used effectively, could potentially help students to move beyond their initial or intermediate conceptualizations about the mathematical ideas involved. As students reflect on their own thinking—both as they prepare their presentations, and react to the questions that are precipitated by their peers and the teacher, they have the opportunity to revise, refine, and extend their ways of thinking about the mathematics, which in this case involved the relationship between area and perimeter. As they do this, their early conceptualizations become increasingly refined. To this end, we analyzed their discussions by identifying models of the relationship between area and perimeter, and revisions and refinements of these models. An additional hypothesis was that by focusing on discourse as one part of a teacher development project, participating teachers would also refine, revise, test and share important aspects of their evolving models for teaching and learning mathematics.

### **Background**

In order to help teachers make the transition from teaching mathematics in more traditional ways that emphasize the execution of procedures and rote memorization, mathematics education researchers met regularly with teachers—both in the context of workshops and in the context of their own classrooms. During these meetings, opportunities were provided for teachers to: deepen their own understanding of the mathematics they were expected to teach, develop insight into the ways in which students build these ideas; and, consider the pedagogical implications of teaching mathematics in new ways. Teachers were encouraged to provide opportunities for the students to develop logical and persuasive predictions, explanations, and justifications; analyze or critique their own solution, or the solution of others; and, consider the ways in which they could refine, revise, monitor, and assess their own work. Teachers were also encouraged to consider the mathematical discourse that was elicited, and how they might begin to use new methods of questioning to encourage students to, for example, defend and justify their solutions, pose interesting hypotheses, and share strategies.

The student activities used in this research were considered to be “modeling problems”. That is, these problem activities had been deliberately designed to provide students with the opportunity to actively explore the mathematics (in this case, concepts involving area and perimeter) as they made conjectures, tested their ideas, and continually refined and shared their understanding of these ideas. (A more complete description of the design characteristics can be found in Schorr and Koellner-Clark, *in press*). The particular activities used in this research will be further described below.

### **Method**

This research took place in a suburban district in the southeast, over the course of a year, as part of a teaching experiment involving middle school mathematics. In this research, we will focus on one seventh-grade teacher. Twenty-four lessons were

documented and we will share the 12th lesson of this sequence. The class consisted of 28 students, 15 girls and 13 boys. All sessions were videotaped and audio taped.

Researcher notes were also carefully collected and transcriptions and detailed narratives of the data were recorded.

A coding scheme was designed to flag elements for the study and then categories were identified similar to qualitative analysis described by Glaser & Strauss, (1967). After this, interpretative and observational procedures were employed, based upon our theoretical framework.

### Results

As noted above, the type of professional development that was employed throughout the study was designed to help the teachers make conjectures about their own classroom practice, test their ideas, and continually refine these ideas based upon classroom activity. The particular aspect of the project, that is, the topic of this paper, related to discourse in the context of student presentations. The activity, which is the focus of the excerpts below, was the third of a series involving the relationship between area and perimeter. The excerpts and analysis provided below will be used to show how this teacher facilitated substantive discourse through the use of questions and interventions during group presentations. The problem activity presented here had several components. First, the students were asked to trace their footprint on a piece of centimeter graph paper. Next, they were to cut a piece of yarn that had the same perimeter as the footprint; and then use that yarn to create a new rectangle. Finally, they were asked to determine if the area of the newly created rectangle would be equal to the area of the original footprint. Students were also asked to explain whether or not finding the perimeter of the footprint was an accurate way to find the area of the footprint. They were also asked to write a letter to their parents explaining the relationship between area and perimeter using the footprint example to lend support to their findings. When discussing her reason for choosing this particular activity, the teacher stated that her goal was to help students determine the relationship between the perimeter and area of a region, especially when perimeter is held constant. In order to encourage students to talk about their ideas as they were working on the problem, she arranged them into groups of three or four. She felt that by using small groups, students would be more likely to share their thinking with each other.

Throughout the lesson, the teacher used various types of questioning techniques including reiterating what the student(s) said, and requesting explanations. When the students had finished working on the problem, the teacher asked the students in each group to justify their solutions using a presentation style format. Each group had to present their ideas, and then respond to questions from the teacher and their peers. The teacher noted that she chose this format because justification of solutions often drives students to examine the validity of their own ideas by testing and refining previously held notions. This, she felt, could potentially cause the students to extend, reject, or

revise their previously held notions.

The following excerpt, in which Andrew shares his work with the class, will illustrate this process, as implemented by the teacher.

Andrew: You can see that I estimated the area of my foot to be 158 cm and the area of the rectangle was exactly 178. I think these estimates are fairly accurate because it was difficult to get a perfect estimate of my foot. I underestimated because I didn't count all of the partial squares. So I think this method is pretty accurate-as accurate as estimating goes..[he goes on to read his letter that is aligned with this thinking]

Robin: I think Andrew's method was accurate-I was doing it a different way but when he showed me why his way worked I could see it. When I did it like him...my estimates [of the rectangle and the footprint] were close too.

Teacher: How did you think about the problem before you used Andrew's method?

Jenny: Well, our feet are smaller, [referring to herself and Robin] so we weren't sure about the shape of the rectangle...my rectangle was more square but then this other way made ours more long and skinny like our foot-doing it Andrew's way made our estimates close.

Teacher: Okay let's have the next group go and try and work off of Andrew, Robin, and Jenny's presentation. Make comparisons between your strategies. You might want to refer back to Jenny's comment about how she made her rectangle more square but then decided to make it more "long and skinny" if you can.

In this excerpt, the teacher attempted to capitalize on the differences between Jenny and Robin's strategy, and the strategy that Andrew used, by calling attention to Jenny's previous method [her "rectangle was more square"-making the area much larger than that of her foot]. She was hoping that by doing this, the students might reflect upon their own strategy and in the process, be able to revise and refine the model they had for thinking about the connection between area and perimeter. In other words, the teacher was attempting to set up a situation where students could make connections and/or revisions to the models they had created.

After careful reflection, she made the decision to select a second group whose solution could potentially push the conversation forward.

James: Well... I think that the perimeter could be the same and the area rectangle could be long and skinny and then the areas would be different because the longer the rectangle the smaller the area. That would be the opposite of the pentomino activity we did last week because then

the area was always 5 but we found different perimeters.

Teacher: Sylvia and Renee [James' other group members] were your ideas similar or how did you look at this problem?

In this excerpt, one student, James, said that the area could be the same and the perimeter different. He was able to extend his previous model for thinking about area and perimeter to include the relationship he noted here. However, he also made a new conjecture when he noticed that the longer the rectangle was, the smaller the area became, even if the perimeter stayed constant.

In order to include the other group members and provide them with an opportunity to add to the discussion, the teacher asked for their ideas.

Sylvia: See each of us did our rectangle different and so we can justify our solution or letter by showing the different areas of the rectangles and none of them are the same as our estimated feet.

Teacher: Jenny, how do their findings relate to what your group found?

As the students considered their justification, the teacher requested that the previous group clarify what appeared to be conflicting solutions and provide valid mathematical evidence for them.

Jenny: Well, Sylvia's rectangle looked like mine before I redid it to look more like the shape of the foot. So they were saying the area of that rectangle was not the same as the area of her foot.

Teacher: What might that tell you about the relationship between area and perimeter?

Robin: Well...I guess I could take the string and make rectangles that had different areas.

Andrew: I still would have thought that since we didn't change the length of the string that the area would have been the same...but I just made two different rectangles [one close to a square and the other with two long sides and two short sides] and found different areas using that piece of string...

Jenny: So I guess the area can be different and the perimeter can be the same or vice versa.

It appears that Robin, Jenny, and Andrew considered the other group's solution and revised their own thinking regarding the relationship between area and perimeter. Robin was the first to verbally consider a different solution but it appeared she became even more convinced as Andrew and Jenny tried to model the new interpretation using the string and graph paper. Andrew actually tried to make different rectangles and

found different areas using his piece of string. This suggested that he was verifying or justifying his new model of the relationship between area and perimeter. Jenny clarified the relationship verbally and then related this idea back to a previously held model.

### Conclusions

Results indicate that this teacher was able to use questioning in the context of student presentations as one way to help students build new models for considering mathematical ideas involving area and perimeter. In this case, the teacher was able to establish a classroom atmosphere in which students could openly talk about their mathematical thinking, and be receptive to the thinking of their peers. This type of discourse and reflection should not be taken for granted, for as Schorr and Bulgar (2002) point out, few of the teachers involved in a large-scale study of classroom practice provided similar opportunities for students. Second, by carefully selecting the order of the presentations, she was able to help students consider discrepancies in their own and their peers thinking. Her careful selection was key in helping students to reconsider their own ways of thinking about the mathematics.

As illustrated in the first excerpt, not all models or notions about area and perimeter remained constant throughout the course of this lesson. In fact, many students directly attributed changes in their own way of thinking to the comments, questions, or ideas of their peers. For example, Robin explained that she changed her method based on Andrew's comments. Her new model for thinking about the relationship between area and perimeter was based on the notion that the rectangle should be the same shape as your foot-long and skinny. More specifically, when perimeter is held constant then the area of the rectangle and the area of their foot should be the same or similar, due to the estimates involved. In discussions between and amongst the teachers, they reported that this type of solution was typical of many groups that they had observed. The teachers felt that it reflected many students' first model of the solution to this particular problem. As this teacher noted, their first attempts "did not take into account all of the information in the problem" and were often "unstable ideas in regards to the concepts of perimeter and area."

In addition to discussions involving the mathematical ideas, the teachers also used the workshop settings to compare the individual characteristics of the group members. Not surprisingly, the development of student ideas varied in all of their classrooms. For example, this particular teacher shared that, as indicated in the first excerpt, Andrew was confident in his first idea and easily persuaded the other group members to use his method. She felt that Andrew "dominated" the discussion in this group and initially was not open to revising his ideas based on Robin and Jenny's ideas. Andrew's "method" provided a visual justification for Jenny and Robin. This finding, albeit not new (Cohen & Goodlad, 1994), clearly impacted the discourse and how students interpreted the relationship between area and perimeter. However, when

the teacher became aware of these differences and was able to use them as a way to leverage discussion of the mathematical concept at hand, many students were able to move beyond their initial ways of thinking.

It is worth noting that the teachers became increasingly aware that deliberate and careful facilitation of student presentations provided at least one way to help students (re)consider the ways in which they thought about the relationship between perimeter and area. Many misconceptions were identified and discussed, and the teachers noted that this didn't happen because they "told" the students what to do, and how to do it. The teachers were able to see firsthand, that as students prepared their presentations, and considered their own, and their peers thinking they were able to move beyond initial or early conceptualizations. Equally important, by focusing on this particular aspect of classroom practice, teachers were able to reveal, test, and refine their overall approach to teaching and learning. They became better able to recognize that students can go through many different "modeling" cycles as they solve a problem activity. And, they were able to consider the role that questioning, both their own, and the students' played in this regard.

# **THEORY AND PRACTICE OF MATHEMATICS EDUCATION REFORM: INCLUDING THE TEACHERS' VOICE<sup>1</sup>**

Azita Manouchehri  
Central Michigan University  
Azita.M@cmich.edu

One hundred and eighty five high school mathematics teachers completed a survey that elicited their level of familiarity with reform-based curriculum and instruction. Teachers were also asked to comment on the value they attached to current guides for instructional redesign as well as the findings of research in mathematics education. Although a majority of the teachers were familiar with and supportive of Principles and Standards for School Mathematics, they were unsure of whether they applied to their own settings. Nearly all teachers found implementing teaching roles difficult to adopt and implement. Only three teachers attached professional value to current reports of research findings on learning and teaching mathematics.

## **Introduction**

What do mathematics teachers think about the recommendations of the reform for teaching and learning? What value they attach to research in mathematics education? How do they characterize their needs and their expectations of research in helping them meet those needs?

These questions address the very nature of what goes on in mathematics classrooms, the perceived images of reform and research by those that serve as both a target and an audience for their agendas, and have implications for mathematics education research community and those responsible for professional development of teachers. The purpose of the current research was to gain insight into the phenomenon of teacher thinking by collecting data relative to the above questions. The study had three specific goals. The first goal was to document teachers' views on the current recommendations for reform in curriculum and instruction. The second goal was to elicit teachers' assessment of the usefulness of current research in mathematics education in advancing their skills in implementing reform-based practice. The third goal was to identify those elements, from the teachers' perspectives, that facilitate instructional change.

## **Background**

National calls for reform in mathematics education propose a vision of teaching that is student centered and inquiry based. The reform documents encourage teachers to focus on helping students develop a conceptual understanding of mathematical ideas. It is recommended that in doing so, teachers must rely on various innovative instructional approaches such as using group discourse, technology, and open-ended exploratory activities (NCTM, 1991; NRC, 1999). These recommendations are grounded in the current convictions shared within the mathematics education research

community about how mathematics is best learned and taught. These convictions are endorsed by a large number of teacher educators across the country and presently guide the design and content of various professional development opportunities teachers are offered.

Despite this widespread enthusiasm of researchers and teacher education practitioners for implementing reform-minded teaching, innovative instruction remains a novelty in school settings (Ball & Cohen, 1998). There is evidence that many teachers are unaffected by the reform (Ball & Cohen, 1996) and continue to teach in a traditional manner (Ball & Cohen, 1998). Researchers have identified several teacher attributes that contribute to this dilemma. Four persistent themes include: teachers' lack of familiarity (and comfort) with a gradual development of the subject matter which prevents them maintaining instructional coherence (Manouchehri, 1998; Manouchehri & Goodman, 1998, 2000); teachers' inability to present mathematics as a chain of interpenetrating concepts rather than as isolated skills due to their narrow understanding of the subject (Kennedy, 1998; Fireston, 1998); teachers' reluctance to conform to new methods of teaching due to a mismatch between their own beliefs about the nature of mathematics and the philosophies that guide the reform recommendations and teachers' reliance on locally driven theories about practice rather than current research on learning and teaching (Tobin, 2001).

In reviewing the content of this body of work on teachers a common denominator prevails. Namely, the results of these studies represent the researchers' (research team's) perceptions of what ought to happen in classrooms, what teachers do not or can not do and the value they attach to the teachers' choice of pedagogy or student learning. In discussing implications, the researchers highlight what may be done to assist teachers to develop the skills they need along with issues that they consider as worthy of further investigation. Although we learn a significant amount from these studies, they also evidence the absence of teachers' voice in deepening our understanding of the complexities associated with instructional change and in shaping the direction of research within the discipline (Goodson, 1996). This omission of teachers' perspectives and views is problematic (Clark, 1996). This is an issue that needs to be addressed if efforts to reform mathematics education are to be successful in real school settings.

### **Research Goals and Methodology**

The overarching goal of the current study was to better understand ways in which mathematics teachers interpret and assess recommendations for instructional redesign, messages of research, and their own role in the broad context of educational reform. In this work I focused on high school mathematics teachers. This was for several reasons. A majority of past research on teaching and teachers has focused on elementary teachers. There is very little knowledge within the mathematics education research community about the professional perspectives of high school mathematics teachers, or their needs.

### Data Collection Instrument

A survey was designed and mailed to 400 high school mathematics teachers across the state of Michigan<sup>2</sup>. In addition to obtaining biographic information on teachers, the survey elicited information on: Factors that serve as catalysts for change in the teachers' knowledge for teaching, elements that teachers find most problematic when implementing reformed-based curriculum and instruction; dimensions of teachers' instruction most influenced by current research on mathematics learning and teaching.

Questions parallel to items on Ohio State Teaching Confidence Scale (Hoy, 1998) were developed and include in the survey. These questions asked teachers to rate their confidence with innovative instructional roles and techniques. Teachers were asked to rank their level of proficiency in implementing aspects of reform minded practice (i.e., use of technology, teaching for conceptual understanding, using problem solving in instruction, using inquiry based methods, sustaining classroom discourse, and mathematics teaching as connection making). They were also asked to identify areas in which they felt they needed professional development.

Lastly, teachers stated the extent in which they were familiar with current research in mathematics education, whether they found such research reports beneficial to their work, and to identify areas that they felt must gain research attention.

### Data Analysis

I used factor analysis to determine relationships among various teacher variables (number of years of teaching, age, gender, post-graduate training, school district, types of professional development activities in which they were engaged within the last 5 years, courses they taught) and their level of knowledge about, and support of, reform based curriculum and instruction as well as research in mathematics education. In doing so, we used a principal-axis factor analysis using Kaser's criterion of Eigenvalues greater than 1 (Borg & Groenen, 1997) in combination with Cattell's Scree Test to determine the number of factors that needed to be considered in the analysis (Kim & Mueller, 1978). In addition, I looked for common patterns of comments among teachers' responses to open-ended questions. Descriptive statistics were obtained to highlight common themes.

### Results

One hundred and eighty five surveys were returned. The sample consisted of 110 male and 75 female teachers. The mean teaching experience of the participants was 21 years. Thirty-two teachers had less than 10 years of teaching experience. Seventy-seven teachers taught in rural, 66 in urban and 42 in suburban school districts. One hundred and sixty one participants were white. Those remaining were of African American and Asian heritage. All teachers taught 9-12 grade mathematics. Thirty-nine participants had teaching responsibilities that included upper division mathemat-

ics courses (Pre-calculus, calculus, and statistics). Others' teaching load ranged from courses in fundamentals of mathematics, mathematical modeling, geometry, Algebra I and II. Forty-two teachers had participated in professional development activities that were content specific within the last five years. Topics of these professional development included technology in instruction, using new textbooks, and authentic assessment techniques. Nearly a half of the participants ( $n = 90$ ) had completed at least one graduate course at the university within the last three years. Sixty-nine teachers had completed a master's degree in curriculum and instruction within the last ten years. Approximately 70% of the participants were familiar with NCTM's Principles and Standards for School Mathematics. Only 8% of the participants stated familiarity with Professional Standards for Teaching Mathematics.

There was a positive correlation between the level of mathematics preparation of the participants and their degree of support of the NCTM's guides for practice. Those teachers with a more sophisticated mathematics background (more coursework in mathematics education) were more supportive of, and confident in their ability to implement innovative curriculum and instruction. Female teachers tended to be more supportive of recommendations of reform for learning and teaching mathematics. In addition, teachers in suburban school districts were more familiar with the standards and found them more applicable to their work. Over 95% of the teachers in urban and rural districts expressed that they found the current guides for instructional change impractical for their settings.

Age, number of hours of involvement in professional development activities, and years of teaching experience did not serve as significant factors on participants' level of support of the reform based instruction. Lastly, only three teachers in the entire sample found merit in current research findings for advancing their professional efforts.

A summary of the teachers' responses to questions that assessed their level of comfort with innovative teaching practices, professional needs, and usefulness of research findings in mathematics education is reported below.

### **Assessment of Reformed-Minded Practices**

Table 1 summarizes the participants' assessment of their own comfort with implementing the type of teaching roles currently advocated by various reform documents. As the data indicate, a majority of the teachers (approximately 70%) found teaching for conceptual understanding, connection making, supporting classroom discourse, technology enhanced instruction, and inquiry based mathematics either difficult or very difficult to sustain. The same percentage of teachers found connecting children's thinking to a mathematical structure as a difficult task to implement as well. Nearly 83% of the participants found accommodating all children's needs also a critical issue in instruction. It is also interesting to note that nearly seventeen percentage of the teachers were unsure of what "teaching for conceptual understanding" and "supporting classroom discourse" entailed.

**Table 1.** Teachers' Reports of Their Level of Comfort With Reform-based Instructional Behaviors

| Teaching Actions                         | Very Easy | Easy | Difficult | Very Difficult | Not Sure What it Means | No Response |
|--|-----------|------|-----------|----------------|------------------------|-------------|
| Teaching for problem solving             | 27        | 59   | 72        | 17             | 0                      | 10          |
| Teaching for conceptual understanding    | 8         | 11   | 17        | 116            | 31                     | 2           |
| Teaching for connection making           | 2         | 25   | 83        | 56             | 19                     | 0           |
| Supporting classroom discourse           | 7         | 11   | 114       | 18             | 35                     | 0           |
| Inquiry based mathematics instruction    | 9         | 31   | 88        | 38             | 9                      | 10          |
| Technology-enhanced explorations         | 17        | 37   | 116       | 15             | 0                      | 0           |
| Teaching reasoning                       | 46        | 34   | 67        | 36             | 2                      | 0           |
| Utilizing multiple representations       | 11        | 35   | 87        | 24             | 25                     | 0           |
| Accommodating <u>all</u> students' needs | 13        | 10   | 132       | 22             | 0                      | 8           |

Table 2 summarizes the teachers' assessment of their ability to foster the type of student behaviors closely tied to reform-based instructional goals. Seventy percentage of the participants expressed it was difficult for them to help students develop the skills to pose mathematical questions in class, learn to apply mathematics, communicate mathematics effectively, listen to peers' arguments and debate accuracy of the ideas. In addition, 73% of the teachers found it either difficult or very difficult to help students appreciate and enjoy mathematics.

#### **Assessment of Their Past Professional Development Opportunities Offered**

In response to the question which elicited teachers' assessment of their past experiences with various professional development opportunities they were offered, an overwhelming majority of the teachers ( $n = 143$ ) rated their experiences as ineffective. One hundred and nine of these teachers claimed the content of the sessions they had attended was either too difficult, or too trivial. Fifty-seven teachers from this

**Table 2.** Teachers' Reports Of Their Level Of Comfort On Fostering Reform-based Learner Behaviors

| Learner Actions                                     | Very Easy | Easy | Difficult | Very Difficult | Not Sure What It Means | No Response |
|---|-----------|------|-----------|----------------|------------------------|-------------|
| Problem solve                                       | 23        | 42   | 93        | 8              | 17                     | 2           |
| Develop conceptual understanding                    | 6         | 45   | 106       | 7              | 21                     | 0           |
| Use technology to pose and solve problems           | 13        | 36   | 118       | 17             | 1                      | 0           |
| Pose mathematical questions in class                | 2         | 21   | 87        | 58             | 11                     | 6           |
| Express their thinking both verbally and in writing | 38        | 59   | 44        | 23             | 16                     | 5           |
| Make mathematical conjectures                       | 12        | 57   | 87        | 23             | 2                      | 4           |
| Approach problems in different ways                 | 59        | 52   | 40        | 34             | 0                      | 0           |

category expressed the content of their workshops either too narrow to have practical merit for long term instructional planning, or too general to have mathematical merit. Twenty-one teachers rated those workshops that focused on the use of technology in instruction as extremely helpful.

### Areas in Need of Professional Development

Teachers were asked to identify areas in which they felt professional development opportunities were of special need to them. Topics most frequently cited by teachers included: Writing lessons that utilize applications of mathematics ( $n = 117$ ), using calculators in lessons ( $n = 174$ ), using computers in lessons ( $n = 112$ ), implementing discovery learning activities ( $n = 153$ ), ways to maintain productive discussions about mathematics among students ( $n = 162$ ), ways to involve/engage all students in mathematics learning ( $n = 177$ ), dealing with diverse abilities and background students bring to class ( $n = 151$ ), convincing students that mathematics is important and useful ( $n = 120$ ), implementing open-ended exploratory activities ( $n = 76$ ), establishing interest

in mathematics and mathematics learning among students ( $n = 171$ ), helping students take charge of their learning ( $n = 84$ ). A moderate number of teachers expressed a need for assistance in finding meaningful activities to use in my instruction ( $n = 53$ ), organizing and monitoring cooperative group activities ( $n = 75$ ), using students' life experiences in my instruction (68), using assessment techniques other than standard tests ( $n = 49$ ). A small number of teachers identified a need for further training in how to facilitate learning rather than telling students what to do ( $n = 13$ ), do long term instructional planning ( $n = 4$ ), explaining "why" mathematical algorithms work the way they do ( $n = 21$ ), deciding which mathematical conventions are important for students to know ( $n = 16$ ), connecting mathematics to other subject areas ( $n = 36$ ), and making connections among various mathematical topics ( $n = 11$ ). Nearly all teachers from urban schools also identified the need to learn more about how to deal with students for whom English is a second language, and help reduce absenteeism. In addition, of particular interest to over 65% of the teachers in rural schools was learning about how to work with limited resources in classroom.

### **Views on Research in Mathematics Education**

Three of the survey questions solicited teachers' views on the agenda and findings of research in mathematics education. First question asked teachers to rank their familiarity with findings of current research in mathematics education from very high (4) to very little (0). Second question asked teachers to rate the findings of current research along a continuum from very useful (4) to not useful at all (0). They were also asked to state the reasons for their rating. The third question asked the participants to identify areas in which they felt additional research was needed.

The mean score for the teachers' ratings on the first question was 3.1 with a standard deviation of 0.4. However, the mean score for the teachers' ratings of the second question was 0.2, with a standard deviation of 0.8. A majority of the teachers felt the current research did not address the level of mathematics they taught ( $n = 117$ ). One hundred and eleven teachers stated they found research reports difficult to understand. One hundred and nine teachers expressed that they felt the body of research failed to provide concrete guides for practice (109). Ninety-two participants claimed those research studies they had reviewed did not focus on answering questions that related to their particular settings. Over 95% of this population taught in rural and urban school districts. Seventy-six teachers claimed the research reports they read did not make sense to them. Fifty-four teachers objected found the research settings artificial, thus, their findings not applicable to their own particular situation. Lastly, twenty-five teachers made statements that indicated a lack of trust for those conducting research in mathematics education (i.e. University people like to tell us what to do).

In order to benefit from research, 141 expressed a need to learn more about how to motivate all students in learning. One hundred and nineteen teachers found it crucial to study and learn about methods to bridge informal explorations to formal mathemat-

ics. Other categories identified by teachers included: Long term student outcomes of teaching concepts ( $n = 51$ ), the influence of block scheduling on learning ( $n = 37$ ), the impact of technology on mathematics learning ( $n = 46$ ). Fourteen teachers stated that they did not know how to respond to the question. Seven teachers did not respond to this question item.

### Discussion

The findings of the study have implications for both research and practice in mathematics education. On the one hand, the results speak to the need for a substantial redesign of professional development opportunities planned for high school mathematics teachers. On the other hand, they point at the chasm between theory and practice in mathematics education.

The participants in the current study found the content of the current visions for practice as manifested in the NCTM documents difficult to understand and implement. They felt they needed specific guides for long-term implementation of the reform minded practices in addition to having access to sustained and relevant professional development opportunities. The teachers' assessment of their own past educational experiences highlighted the ineffectiveness of professional development activities that fail to take into account the various background knowledge and experiences they possess. For a large number of teachers issues surrounding motivating student learning and meeting individual needs of a diverse student population were of paramount complexity. Certainly, as the teachers' reports evidenced there were differences in what teachers identified as critical to their work according to whether they taught in urban, suburban, or rural school districts. Differences among intellectual and professional needs of a diverse teaching population certainly calls for planning differentiated educational opportunities for them. This is much in line with current guides for teachers' own classroom practice.

The data also indicate that the participants in this study found little merit in current reports of research findings in mathematics education. A majority of the participants found this body of work of little help and value when organizing and implementing instruction and instructional change. For a large number of them both the context and content of reported research on learning and teaching mathematics was foreign- too abstract to have practical merit. Although some of the participants objected to the form in which the findings were reported, their major dissatisfaction rested upon what they perceived as the narrow focus and range of these studies and their inability to shed light on how to resolve dilemmas in their settings. This pragmatic expectation of research by practitioners is neither new nor unreasonable. Certainly, good practice is grounded in sound theory. In turn, the test of a good theory is whether it can guide practice. In order for practitioners to systemically rely on research findings when designing instruction they must first find them meaningful and relevant. They must also believe the conditions under which studies were completed matched the circumstances under

which they work. Areas of research identified by teachers provide promising grounds for conceptualizing ways in which professional needs of teachers may be met and possibly link the domains of research and practice.

# LEARNING TRAJECTORIES AS TOOLS FOR SUPPORTING TEACHER CHANGE: A CASE FROM STATISTICAL DATA ANALYSIS

Kay McClain

Vanderbilt University

kay.mcclain@vanderbilt.edu

This paper provides an analysis of a Teacher Development Experiment (cf. Simon, 2000) designed to support teachers' understandings of statistical data analysis. The experiment addresses the following research question: Can the results from research conducted in a middle-grades mathematics classroom be used to guide teachers' learning? In both cases, activities from an instructional sequence designed to support the development of ways to reason statistically about data were the basis of engagement. Analyses of the episodes in this paper document that the learning trajectory that emerged from the teachers' activity did, in many significant ways, parallel that of the students.

## Purpose

The purpose of this paper is to provide an analysis of the development of one group of teachers' understandings of statistical data analysis. The analysis builds on the literature on students' understandings by taking prior research as a basis for conjectures about means of supporting teachers' development. In particular, the work reported in this paper is part of a larger project focused on supporting the development of professional teaching communities.<sup>1</sup> The project builds on prior work in classrooms by taking analyses of two classroom teaching experiments as its starting points. The first teaching experiment was conducted in the fall semester of 1997 with a group of 29 seventh graders. The focus of the experiment was on ways of supporting students' understanding of statistical data analysis. As part of this work, the research team<sup>2</sup> developed an instructional sequence and accompanying computer-based tools for analysis. The intent of the instructional sequence was to support middle-school students' development of sophisticated ways of reasoning statistically about univariate data. The overarching goal was that they come to reason about data in terms of distributions. Inherent in this understanding is a focus on multiplicative ways of structuring data. The second teaching experiment was conducted the following year with a subset of the students and focused on covariation. A second instructional sequence and computer-based tools were developed for this phase of the project. Analyses of these teaching experiments therefore provided a basis for collaborations with the teachers by offering a tested and refined conjecture about a learning route for students and the means of supporting its development (cf. Cobb, 1999; Cobb, McClain, & Gravemeijer, in press; McClain & Cobb, 2001a; McClain, Cobb, & Gravemeijer, 2000).

The intent of the teacher collaboration was to build from the mathematical practices that emerged in the course of the classroom teaching experiment. Fundamental

to this effort was support of the development of the teachers' content knowledge. The hypothesis was that the same general learning trajectory (i.e., a parallel progression of conceptual development) could serve as a basis for guiding the mathematical development of the teachers. This trajectory served as a conjecture about the learning route of the teachers and the means of supporting their development. During the collaboration, the conjecture was continually being tested and refined in the course of interactions with the teachers. The trajectory therefore offered a conjectured route through the mathematical terrain. This conjecture included not only taking the classroom mathematical practices as a basis for the learning route of the teachers, but also taking the accompanying *means of support* as tools for supporting the emergence of the mathematical practices. These tools included the choice of tasks, the use of computer-based tools for analysis, the use of the teachers' inscriptions and solutions, and the norms for argumentation.

In the following sections, I begin by outlining the instructional sequence. I then describe the methodology used in the analysis followed by a description of the data corpus. Against this background, I provide an analysis of episodes from the work sessions intended to document the teachers' developing understandings of statistical data analysis. I conclude by returning to the conjectured learning trajectory as a means of supporting teachers' mathematical development.

### **Instructional Sequence**

In developing the instructional sequence for the seventh-grade classroom teaching experiment, our goal was to develop a coherent sequence that would tie together the separate, loosely related topics that typically characterize American middle-school statistics curricula. The notion that emerged as central from our synthesis of the literature was that of distribution. In the case of univariate data sets, for example, this enabled us to treat measures of center, spreadout-ness, skewness, and relative frequency as characteristics of the way the data are distributed. In addition, it allowed us to view various conventional graphs such as histograms and box-and-whiskers plots as different ways of structuring distributions. Our instructional goal was therefore to support the development of a single, multi-faceted notion, that of distribution, rather than a collection of topics to be taught as separate components of a curriculum unit. A distinction that we made during this process which later proved to be important is that between reasoning additively and reasoning multiplicatively about data (cf. Harel & Confrey, 1994; Thompson, 1994; Thompson & Saldanha, 2000). Multiplicative reasoning is inherent in the proficient use of a number of conventional inscriptions such as histograms and box-and-whiskers plots.

As we began mapping out the instructional sequence, we were guided by the premise that the integration of computer tools was critical in supporting our mathematical goals. The instructional sequence developed in the course of the seventh-grade teaching experiment in fact involved two computer minitools. In the initial phase of

the sequence, which lasted for almost six weeks, the students used the first minitool to explore sets of data. This minitool was explicitly designed for this instructional phase and provided a means for students to manipulate, order, partition, and otherwise organize small sets of data in a relatively routine way. When data were entered into the tool, each individual data value was shown as a bar, the length of which signified the numerical value of the data point (see Figure 1).

Figure 1. Data displayed in the first minitool.

A data set was therefore shown as a set of parallel bars of varying lengths that were aligned with an axis. Its use in the classroom made it possible for students to act on data in a relatively direct way. The first computer minitool also contained a value bar that could be dragged along the axis to partition data sets, to estimate the mean or to mark the median. In addition, there was a tool that could be used to determine the number of data points within a fixed range. Students' activities with this tool supported the emergence of the first mathematical practice, that of *exploring qualitative characteristics of collections of data points* (Cobb, 1999).

The second computer minitool can be viewed as an immediate successor of the first (see Figure 2). As such, the endpoints of the bars that each signified a single data point in the first minitool were, in effect, collapsed down onto the axis so that a data set was now shown as a collection of dots located on an axis (i.e. an axis plot as shown in Figure 2). The tool offered a range of ways to structure data. The options included: (1) making your own groups, (2) partitioning the data into groups of a fixed size, (3) partitioning the data into equal interval widths, (4) partitioning the data into two equal groups, and (4) partitioning the data into four equal groups. The key point to note is that this tool was designed to fit with students' ways of reasoning while simultane-

Figure 2. Data inscribed in the second minitool.

ously taking important statistical ideas seriously. The second tool made possible the emergence of the second mathematical practice, that of *exploring qualitative characteristics of distributions* (Cobb, 1999).

As we worked to outline the sequence, we reasoned that students would need to encounter situations in which they had to develop arguments based on the reasons for which the data were generated. In this way, they would need to develop ways to analyze and describe the data in order to substantiate their recommendations. We anticipated that this would best be achieved by developing a sequence of instructional tasks that involved either describing a data set or analyzing two or more data sets in order to make a decision or a judgment. The students typically engaged in these types of tasks in order to make a recommendation to someone about a practical course of action that should be followed. An important aspect of the instructional sequence involved talking through the data creation process with the students. In situations where students did not actually collect the data themselves, we found it very important for them to think about the types of decisions that are made when collecting data in order to answer a question. The students typically made conjectures and offered suggestions about the information that would be needed in order to make a reasoned decision. Against this background, they discussed the steps that they might take to collect the data. These discussions proved critical in grounding the students' data analysis activities in the context of a recommendation that had real consequences.

### Methodology

The general methodology falls under the heading of a Teacher Development Experiment (TDE) (cf. Simon, 2000). This methodology is derived from the construc-

tivist teaching experiment (cf. Cobb & Steffe, 1983; Steffe & Thompson, 2000) and whole-class teaching experiments (cf. Cobb, 2000) by acknowledging that a team of “knowledgeable and skillful researchers can study development by engaging in fostering development through a continuous cycle of analysis and intervention” (Simon, 2000, p. 336). The distinction between the TDE and the teaching experiment is that the TDE is concerned not only with the mathematical development of the participants (i.e., the preservice teachers), but also with their professional development. In this way, the TDE can be characterized as a “whole-class teaching experiment in the context of teacher development” (p. 345).

The breath of issues both addressed and acknowledged in the TDE indicates the complexity of teacher professional development. Simon (2000) indicates one source of this complexity when he observes that whereas the focus in a classroom teaching experiment is on students’ mathematical development, collaborations with preservice teachers are concerned with both their pedagogical development and their mathematical development. I build from Simon by accounting for both the mathematical and pedagogical issues that emerged over the course of the TDE.

The approach I took when conducting retrospective analyses of the data generated during the TDE involves a method described by Cobb and Whitenack (1996) for analyzing sets of classroom data. This method is an adaptation of Glaser and Strauss’ (1967) constant comparative method. The initial orientation for a retrospective analysis is provided by the tentative and eminently revisable conjectures that were developed both prior to and while actually conducting the TDE. The method involves continually testing and revising conjectures while working through the data chronologically. These conjectures might focus on such issues as the evolution of the preservice teachers’ understandings of the mathematics or the means by which individual students’ learning was supported and organized. This constant comparison of conjectures with data results in the formulation of claims or assertions that span the data set but yet remain empirically grounded in the details of specific episodes.

The particular lens which guided the analysis of the data was a focus on the norms of *what counts as an acceptable mathematical argument and justification* and *what counts as an acceptable pedagogical argument and justification* (cf. McClain & Cobb, 2001b; Yackel & Cobb, 1996). I was interested in documenting changes in the teachers’ conceptions of what counts as an acceptable mathematical argument in the course of mathematical investigations of data. It was therefore important for the teachers to participate in exploring the mathematics that underlies the analysis not only to ground their own investigations, but to have them wrestle with the mathematics and how best to justify solutions in the context of the posed analysis.

I was also interested in documenting shifts in the teachers’ conceptions of what counts as an acceptable pedagogical argument in the course of discussions of classrooms. It would not only be important that the teachers understand the numerous and

varied aspects of practice, but also that they be able to justify in the course of discussion their rationale for a particular stance or judgment.

### **Data Sources**

Data for the study include videotape of monthly and summer work sessions in addition to field notes taken by a research assistant. Copies of the teachers' work and their students' work are also included. In addition, data sources include classroom observations and follow-up interviews to develop accounts of practice (cf. Simon & Tzur, 1999) that can be used to document changes in the teachers' practice. For this reason, sites of data collection include the work sessions and the teachers' classrooms.

### **Results of Analysis**

The reader will recall that the first mathematical practice that emerged in the seventh-grade classroom was that of exploring qualitative characteristics of data points. The initial activities in support of the emergence of this practice involved the teachers analyzing data on the braking distances of 10 each of two makes of cars, a coupe and a sedan. I introduced the task by first talking through the data creation process with the teachers. I then presented the data by giving the teachers paper copies of the data inscribed in the first minitool as shown in Figure 1. I asked the teachers to work at their tables to decide which make of car they thought was safer, based on these data. My decision to use printouts of the data was based on my own experience in working with students on these tasks. I had noticed that when students were asked to make initial conjectures based on analysis of the printouts, their activity on the computer tool seemed more focused. They used the features of the tool to substantiate their preliminary analysis instead of exploring the structures that resulted from the use of the features. In addition, they focused more on features of the data sets such as clusters. I was also curious to see if the tools we had designed offered the teachers the means of analyzing data that fit with their initial, informal ways of analyzing the data.

As the teachers began their analyses, most of them initially calculated the mean of each set of data. They subsequently judged that measure to be inadequate for making the decision and proceeded to find ways to structure the data that supported their efforts at analysis. In this process, they used vertical lines drawn in the data to create cut-points and to capture the range of each set. As an example, one teacher noted that all of the coupes took over 55 feet to stop whereas four of the 10 sedans were able to stop in less than 55 feet. Other teachers focused on the "bunched-up-ness" of the coupes and reasoned that a consistent braking distance was an important feature.

I found these ways of reasoning significant for two reasons. The first was that the ways of structuring that they were creating with the drawn lines paralleled the features that we had designed on the tool. This implied that the tool would be a useful resource in supporting their analysis. The second was that their ways of reasoning about the

data were consistent with the methods that we saw emerge in the seventh graders' activity. It therefore appeared that the conjectured learning trajectory could guide the mathematical development of the teachers.

As the teachers discussed the results of their analysis in a whole-group setting, I introduced the first computer minitool as a resource for sharing their ways of structuring the data. I used a projection system to make the data sets visible to the group and, as the teachers explained their analysis, I used the features on the minitool to complement their explanations. As an example, as the teachers talked about the "bunched-upness" of the data sets, I activated the range tool so that they could identify the extremes in each data set. The teachers found this support helpful and were easily able to use the features on the tool to mirror their earlier activity with drawn lines.

In the remainder of the session, the teachers analyzed a second set of data on the longevity of two brands of batteries. Their analyses were again focused on cut points and clusters. These ways of reasoning parallel what we found in analysis of the seventh graders' activity. In particular, Cobb (1999) notes that in the seventh-grade classroom "[t]he characteristics of data sets that emerged as significant in this discussion and in the subsequent classroom sessions in which the first minitool was used included the range and maximum and minimum values, the number of data points above or below a certain value or within a specified interval" (p. 17). The significant difference between the seventh-grade students and the teachers was that the teachers were able to talk about the number of data points above or below a cut point in terms of percentages (or ratios) of the whole. Further, they could reason probabilistically such as arguing that "you have a 30% chance of getting a bad battery" with a Brand A. Their arguments therefore appeared to be multiplicative in nature.

A shift to the second minitool and a focus on the second mathematical practice—exploring qualitative characteristics of distribution—began with the introduction of the speed trap task. After a lengthy discussion of the data creation process, the teachers were shown printouts of data on the speeds of two sets of sixty cars (see Figure 2). The first were recorded on a busy highway on a Friday afternoon. The speeds were recorded on the first sixty cars to pass the data collection point. The second set of data was collected on a subsequent Friday afternoon after a speed trap had been put in place. The goal of the speed trap (e.g., issuing a large number of speeding tickets by ticketing anyone who exceeded the speed limit by even 1 mph) was to slow the traffic on a highway where numerous accidents typically occurred. The task was to determine if the speed trap was effective in slowing traffic.

As the teachers worked on the printouts of the data, most of them created cut points at the speed limit and reasoned about the number of drivers exceeding the speed limit both before and after the speed trap. They used a range of strategies including ratios and percentages. Further, none of the teachers calculated the mean. One teacher focused on the shape of the two data sets and noted that at first it "looked

like a Volkswagen Beetle” and then it “flattened out like a large Town Car.” I found this particularly significant because it was the first occasion where a teacher found a way to describe the shape of the distribution. I capitalized on her solution and recast it in terms of “hills.” My reason for doing so was grounded in our earlier work in the seventh-grade classroom where a similar incident had occurred with this same data set. For the students, the notion of the hill was pivotal in shifting their reasoning from viewing data sets as collections of points to distributions (cf. Cobb, 1999; McClain & Cobb, 2001a; McClain, Cobb, & Gravemeijer, 2000).

The significance of this shift became apparent in the next session when I introduced a task containing data sets with unequal numbers of data points. In the task, two sets of AIDS patients were enrolled in treatment protocols — a traditional treatment program with 186 patients and an experimental treatment program with 46 patients. T-cell counts were reported on all 232 patients (see Figure 3).

Figure 3. AIDS data displayed in the second minitool.

As the teachers worked on their analysis, they initially noted that the clump, cluster, or hill of the data shifted between the two groups. This was a significant aspect of the distributions and one on which they focused as they continued their analysis using the second minitool. In their work at the computers, they found ways to characterize this shift including creating cut points and reasoning about the percentage of patients in each group with T-cell counts above the cut point. They, like the seventh grade students, noted that that cluster of T-cell counts in the traditional treatment program was below the cut point whereas the cluster of T-cell counts in the experimental was above.

The teachers were also able to use the features of the computer tool to partition the data to support their arguments. One such feature, *four equal groups*, partitions the data into four collections such that each contains 25% of the data. From a design standpoint, we viewed this as a precursor to a box and whiskers plot. The teachers were able to use this feature in conjunction with another that caused the data points to

be hidden, leaving only the partition lines. When the teachers structured the data with the *four equal groups* option and the data hidden as shown in Figure 4, they were able to formulate arguments such as, “Seventy-five percent of the experimental treatment is in the range of only 25% of the traditional treatment.” “If you use the experimental treatment, you have a 75% chance of getting a T-cell count above 525 and only a 25% chance with the traditional treatment.” Arguments such as these indicated their ability to reason multiplicatively about the distributions.

Figure 4. AIDS data structured into four equal groups with data hidden.

### Conclusions

As a result of the parallel developments between the seventh-grade students and the teachers, it appears that the underlying learning trajectory that guided the seventh-grade students' development offers the means of supporting teachers' development of understandings of statistical data analysis. However, there were significant differences in the mathematical development of the teachers. In particular, multiplicative reasoning was a goal in the learning trajectory for the seventh grade students. The tasks and tools were designed to support the emergence of problem situations that would problematize direct additive comparisons and create a need for multiplicative ways of reasoning about the data. For the teachers, multiplicative ways of reasoning were a tool that was available from their initial explorations. The goal for the teachers then became to make explicit the importance of task situations where multiplicative ways of reasoning are necessary (e.g., unequal numbers of data values in the two data sets). For this reason, discussions of multiplicative structures among the teachers took

the perspective of a *teacher* instead of a *student*. It was necessary to create situations where the teachers had to reason about ways to initiate shifts in their own students' strategies.

A similarity that emerged across the two situations was the use of cut points as an accepted way to make a statistical argument. A choice of cut point was a common form of warrant in creating databased arguments. The similarities between the students' and teachers' choices of cut points are very striking, as is the choice of backing for these warrants. This normative way of reasoning about data can then inform future efforts by feeding forward to the realized learning trajectory in both situations.

### Acknowledgements

I would like to thank the special group of teachers discussed in this paper for allowing me to participate with them in their professional endeavors. The research reported in this paper was supported by the National Science Foundation under grant REC-9814898 and by the Office of Educational Research and Improvement under grant R305A6007.

## **RESPONSIVE DESIGN: CREATING A SCAFFOLDING SYSTEM TO SUPPORT TEACHER PROFESSIONAL DEVELOPMENT**

Chandra Hawley Orrill, Evan M. Glazer, & A. Kursat Erbas  
University of Georgia  
corrill@coe.uga.edu

In this presentation we look at the implementation of instructional design principles to support teachers using the InterMath professional development system. In response to needs identified through pilot testing and interviews, we have explored ways to further support participants in the online system as they become engaged in solving complex, open-ended problems. Our needs analysis identified two specific kinds of scaffolds that needed to be developed: one focused on supporting teachers in applying problem-solving principles, the other focused on supporting geometric constructions as a tool for problem solving. This presentation will explore the issues teachers raised, how we determined the scaffolding needed, and what the forms of the two systems is taking. We will also discuss the rapid prototyping design path we are taking in our development effort.

### **Introduction**

InterMath<sup>1</sup> (<http://www.intermath-uga.gatech.edu>) is a technology-intensive professional development experience for middle school mathematics teachers. The professional development effort is aimed at furthering teachers' mathematics knowledge by immersing teachers in a technology-rich mathematical investigation environment. The model upon which InterMath is based assumes that teachers who experience learning in a rich, exploration-based environment will more readily transfer these kinds of experiences to their classrooms. The centerpiece of the InterMath experience and website is an extensive set of open-ended mathematical investigations that can be explored using various technologies (e.g., Excel or Geometer's Sketchpad). These investigations are central to the semester-long workshop as teachers are encouraged to explore a particular set of explorations (e.g., triangles or functions), choose problems that intrigue them, work those investigations, and write-up the solutions, along with extension activities.

Unlike the traditional "make and take" professional development experiences, InterMath does not aim to provide teachers with activities they can take back to their classroom and use. Instead, InterMath provides teachers with opportunities develop both their understanding of mathematics and their ideas about what it means to learn and teach mathematics. Interestingly, in our pilot workshops, many teachers had some degree of success using the InterMath materials as "make and take" – they take the investigations back to their classrooms and implement them almost exactly as they experienced those activities in the InterMath workshop.

InterMath is in its fourth year of development and implementation. During the pilot workshop offerings in Year 2, there were two InterMath workshops conducted

by two different faculty members. One workshop was offered near Atlanta as the first course in a cohort-based graduate degree program for middle school teachers. This workshop was taught by a mathematics education professor who is also one of the developers of the InterMath program. The other workshop was offered at the University of Georgia campus by a professor of mathematics. The participants in the UGA workshop received staff development credits for their experience, as well as a stipend.

As a part of the pilot workshops, we were able to interact with teachers using the InterMath materials to better understand how they worked. The information collected as part of this effort has allowed us to carefully examine both how InterMath works and how we might improve it. This kind of iterative, responsive design based on participant feedback had formed the basis of our continuing design efforts. This paper explores this design effort.
